A male child, aged 4 years, was transferred to the surgical side on October 4th, 1927, with the following history. He had a right-sided inguinal hernia which on successive occasions had been presenting more difficulty in reduction. He had a status lymphaticus, with a chronic obstinate cough associated with dyspnoea, and a definite record of dangerous idiosyncrasy to general anaesthesia. He had been circumcised two years or so previously under a local anaesthetic. He was of a peevish, apathetic temperament.

On this occasion (October 4th) he exhibited tenderness over the hernia. The hernia also presented a peculiarly solid consistence.

co.) and brandy or champagne, except in the presence of flatulence. Stimulants should be given whether food was being taken or not. Ammonium carbonate should be reserved for patients who had both pneumonia and bronchitis. Camphor in oil was useful, and suprarenal extract was a good vasomotor stimulant, but its administration required careful watching in cases of elderly people with arterio-sclerosis. Pituitrin was beneficial in the presence of abdominal distension. Venesection should only be performed in special cases when there was evidence of right-sided cardiac failure.

With reference to specific medication, Sir Thomas Horder discussed the various methods which had been strongly advocated from time to time, including the mixture of iodides and creosote, nucleic acid, and sodium uncininate; he did not favour these methods, but approved the administration of large doses of sodium bicarbonate to combat the acidosis due to protein destruction. Though there was as yet no potent antiserum an antipneumococcal serum might be recommended, since at any rate it did no harm; it should be given early, and in large doses. It was suggested that the ordinary pneumococcal vaccine might be employed in small doses, or a sensitized vaccine with an antiserum given in larger doses. Sir Thomas Horder mentioned immunogen, which was made from the washings of the cultivated organisms; he said that this substance was almost entirely free from protein, and its administration had produced remarkable results. Half a cubic centimetre should be given twice in the first twenty-four hours, and 1 c.cm. twice in the second.

A good discussion followed the lecture, questions being asked by several members. In reply to one with reference to sleep, Sir Thomas Horder said he had found medinal in  $7\frac{1}{2}$ -grain doses useful as a hypnotic. When acute restlessness and delirium were present he employed a mixture of  $1\frac{1}{2}$  drachm of ammonium bromide, with 1 to  $1\frac{1}{2}$  drachms of syrup of chloral, which was given two-hourly so long as required.

On the proposal of Dr. MANKELL, seconded by Mr. COLIN MACKENZIE, a very hearty vote of thanks was accorded to Sir Thomas Horder for a most interesting and instructive lecture.

## Reports of Societies.

### THE CARRIER PROBLEM.

At a meeting of the Medical Society of London, held on March 12th, with the president, Mr. H. W. Canson, in the chair, a discussion took place on the carrier problem.

Dr. J. E. MCCARTNEY, in opening, said that the carrier problem was becoming of increasing importance to the epidemiologist, to the bacteriologist, and to the physician. Its economic importance also could not be ignored, for it was estimated that each carrier in a Metropolitan Asylums Board institution cost £4 per week to maintain, and there were often as many as forty to fifty carriers in any one hospital, so that the cost in London alone was considerable. The subject of the carrier was so vast, he said, that he proposed to deal with it from the point of view of the physician, and also only with the human carrier of infection. There were many diseases which were thought to be distributed by carriers, and he would define a carrier as an individual who harboured and transmitted a pathogenic micro-organism without showing the usual evidences of infection. Carriers were of two main types. There was, first, the well-known convalescent carrier, of especial importance in diphtheria and typhoid fever. All patients suffering from these diseases were in a sense carriers, but they showed evidence of the disease. As this evidence disappeared during convalescence they became temporary carriers, and after an arbitrary period—twelve weeks in the case of diphtheria—if such convalescent patients still harboured pathogenic organisms they became classed as chronic convalescent carriers. The second group consisted of contact carriers, of great importance in certain respiratory tract infections. A contact carrier acquired the micro-organism from some sufferer from the disease, but showed no sign of the disease himself. Sometimes his resistance was

eventually broken down, and he succumbed; such cases were known as "incubation carriers." The contact carrier usually harboured the organism only for a short time, but occasionally the chronic contact carrier developed as a result of the organism settling down in the nose and throat. Dealing next in more detail with certain specific diseases, the speaker mentioned diphtheria, in which the chronic convalescent carrier was of great importance, being the commonest type of carrier in the general community. The important point about such carriers was that the organisms they harboured were virulent. For testing such virulence intracutaneous tests on guinea-pigs were used, and the speaker emphasized that a person carrying a non-virulent type of diphtheria bacillus could not give rise to a fresh case of diphtheria. All attempts to alter such organisms into virulent forms failed, and no return cases ever occurred from non-virulent carriers. More than half the cases investigated with morphological diphtheria bacilli were proved to be non-virulent, and this was especially marked in ear cases. Such important results led to the release of many people from an irksome quarantine, but it was essential that the virulence tests should be carried out with great care, and difficulty was sometimes experienced because the same carrier might harbour both virulent and non-virulent organisms at the same time.

Following the intensive study of a large number of diphtheria carriers, Dr. McCartney said he had established that the growth of organisms from such cases was often slow at first, and after this "lag period" the diphtheria bacillus grew more rapidly, although such cultures should be left for forty-eight hours instead of the usual twelve hours adopted in isolating the bacilli from active cases. This led to another important consideration, for despite the carriers of virulent bacilli comparatively few people were infected in this way, and it was suggested that because of this lag period there was time for those attacked by the bacillus from a carrier to eliminate the organism from the system before it did any harm. The intermittent nature of the carrier was also important, and at the North-Eastern Hospital it was now the rule that a patient must have six consecutive negative cultures during a period of six weeks before being discharged as cured. On the whole, it was the milder cases which were more likely to become carriers, and it was commonest in small children. The Schick test was negative in all carriers. The organism in the case of carriers had an "extra-corporeal" existence in the products of inflammation caused by other organisms, and if such inflammation was dealt with the carrier state disappeared. In 95 per cent. of diphtheria carriers some pathological defect was found, such as diseased tonsils, chronic rhinitis, deflected septum, etc. When infection was present in the tonsils, usually of the buried septic variety with deep crypts, tonsillectomy would effect a cure in nearly all cases. Nasal carriers were more difficult to deal with owing to the anatomical peculiarities of the very young subjects. In treatment each case had to be considered on its merits; when it was established that the organism present was virulent, then the nose and throat must be dealt with. In the nasal carriers vaccines made from the predominating organism causing the rhinitis might help in about 30 per cent. of cases, and it might be necessary to persist until a particular organism was found which was causing the actual condition favourable to the presence of diphtheria bacilli. In other cases the use of a warm alkaline nasal douche was most effective as long as it was continued. In some cases exploration of the antrum had shown the deep-seated nature of the infection. Dealing next with the enteric group of infections, Dr. McCartney said that the chronic convalescent carrier was of most importance, and probably about 5 per cent. of sufferers from typhoid became carriers, the rate being higher in rural than in urban districts. The faecal carrier accounted for 93 per cent. of cases, and there was usually a chronic cholecystitis present. It was important in examining such cases to secure the contents of the small intestine by means of a colonel purge, since in formed stools the typhoid bacillus might have been destroyed by putrefactive organisms in the large intestine. Urinary carriers were rarer, but more dangerous to the community, especially the male urinary carrier who micturated several times a day in

odd places, particularly in rural areas. The purulent type of typhoid carrier was rare. Females accounted for 80 per cent. of all typhoid carriers, and the state was rare in children. Dealing with the detection of typhoid carriers, the speaker mentioned an outbreak of the disease at a mental hospital with 2,000 patients and 800 staff. Despite the immense difficulties involved, a complete investigation was carried out and ten carriers were isolated. The remaining patients were treated with T.A.B. vaccine, with the result that the hospital had been kept free for two years, except for one sporadic case. The Widal reaction was of little use in detecting carriers, and Dr. McCartney stated that his experience with other special tests was disappointing. Treatment of such carriers was unsatisfactory, since removal of the gall-bladder was not always successful and perhaps not justifiable. It seemed to be better to enlist the co-operation of the patient by laying down rules of personal hygiene. Public health regulations were unsatisfactory, since the State had no power to insist on the treatment of carriers.

Dr. McCartney then mentioned carriers of amoebic dysentery who might harbour the cysts for years with vague symptoms, but who responded to correct treatment. In cerebro-spinal fever it was the contact carrier who caused spread directly from person to person, and the organism might go through several individuals without causing the disease. In the epidemic season, and especially in camps and barracks, the carrier rate became very high. The site of infection was usually the upper respiratory tract, and isolation of the organism consisted largely in distinguishing it from other Gram-negative cocci. Dealing lastly with scarlet fever, Dr. McCartney mentioned that it was becoming a serious problem as to whether this disease was spread by carriers. Of a group of 300 patients, more than half still had the haemolytic streptococci in the throat at the end of seven weeks, although the rate was much lower when the wards were less busy. The question of whether scarlet fever patients should all be examined and detained until free from such infection seemed to open up too big a proposition.

Dr. J. FREEMAN pleaded for an extension of the original idea of the carrier. The old conception of the convalescent carrier, as in the case of typhoid, had already been extended to cover the incubation and the contact carrier. He believed that many cases of para-enteric infections were spread by carriers: patients often suffered from these diseases for years without coming for treatment, and he believed that such cases were the cause of just as much misery in the community as typhoid and dysentery. Just as in tuberculosis the person with tubercle bacilli in the sputum, but no clinical signs of phthisis, was regarded as a carrier, so the woman with chronic gonorrhoea, without any obvious sign of disease, was a carrier, and the main function of venereal disease clinics was to protect the community from such carriers. A man with septic gums was also capable of transferring such infection to his neighbours, and by spraying out streptococci such a person might cause a whole variety of diseases in other individuals. It was also possible for a person to carry an infection which caused trouble elsewhere in his own body; such a person could be called an "auto-carrier," and in attempting prophylactic antiscarlatinal vaccination a lighting up of some septic focus, where the offending organisms were being carried, was not uncommon. In conclusion Dr. Freeman stated that he held that every individual was a carrier and that the bulk of infection was due to carriers.

Sir JOHN BROADBENT mentioned some of the difficulties in relation to carriers of the acute infectious fevers. He agreed that tonsillectomy would cure the throat carrier of diphtheria, and he thought that carriers were more frequent in the time of epidemics. In regard to scarlet fever there were many difficulties. About 80 per cent. of all cases of scarlet fever failed to give any evidence of contact with another case. In one case of a small girl he had evidence that she had carried scarlet fever infection for ten weeks after discharge from hospital as cured.

Mr. ZACHARY COPE thought it was justifiable to remove the gall-bladder in chronic typhoid carriers since gall-stones might form. He also mentioned the use of the

duodenal tube to drain the gall-bladder, quoting a case of Lyons's which had been rendered free from infection by this method after having been a carrier for twenty years. He asked whether whooping-cough was transmitted by carriers.

Dr. A. FEILINO described a case of enteric infection in a young man, aged 23, who developed an attack of acute cholecystitis six weeks after paratyphoid fever. An attempt to deal with this case by removal of the gall-bladder had failed, and it had not been possible to get a tube to pass into the duodenum. He asked for advice as to what could be done. Mr. ZACHARY COPE suggested that the mucous membrane of the gall-bladder should be destroyed at a new operation. Dr. McCARTNEY, in reply, stressed the importance of remembering both the parasite and the host in all carrier conditions.

## NARCOLEPSY.

At a meeting of the Section of Neurology of the Royal Society of Medicine, held on March 8th, with the president, Dr. EDWIN BRAMWELL, in the chair, a discussion took place on narcolepsy.

Dr. S. A. KINNIER WILSON, in opening, referred to the fact that, although this condition had been well described many years ago, there was no reference to it in the indexes of *Brain* since 1899 until Dr. W. J. Adie's thesis of eighteen months previously. Dr. Wilson said that his interest in the subject began when he was house-physician to Sir William Gowers in 1907, and he had been on the look out for the disorder for twenty years, although it was only within recent times that he had met it. He had seen several cases in the last year, and it had been suggested that this apparent increase in the occurrence of the condition had something to do with the times through which we were passing. He did not consider, however, that the increase in narcolepsy had anything to do with the outbreak of encephalitis lethargica, since some of his own cases dated their first attacks long before 1918. He argued that narcolepsy cannot be regarded as a disease, but it was rather a symptom—a disordered function of sleep—and he preferred to speak of the narcolepsies. He thought narcolepsy was not an ideal word, and he suggested "hypnolepsy"—a falling into sleep—or Sir William Gowers's suggestion of twenty years ago, "somnolysis." Dealing next with his recent cases Dr. Wilson first mentioned a youth who for two and a half years had had irresistible attacks of sleep, and also the peculiar but well-known phenomenon of falling to the ground powerless under the influence of emotion—the condition of cataplexy. A second patient developed cataplectic attacks, and, later, began to have irresistible impulses to sleep. This case had been examined in the cataplectic state, when the knee-jerks were found to be absent and the plantar response extensor. Two minutes after this, when the man had recovered, the reflexes were found to be normal, while the patient had been conscious the whole time. A third patient presented irresistible impulses to sleep and of cataplexy, both these features of attacks of sleep and of cataplexy, but, in addition, also sometimes suffered from cataplexy or trance, in which he was unable to move a muscle. Dealing with the classification of the narcolepsies Dr. Wilson divided them into those cases with attacks of sleep and of cataplexy and those with prolonged sleep only. Of the first group he had collected forty-five cases from the literature of the last forty years, and it certainly appeared to be more common at the present day. Most of the cases of prolonged sleep approached the region of the symptomatic narcolepsies, and it had been known for years that lesions of the brain in the region of the third ventricle were often associated with pathological sleep. Dr. Wilson believed that all the primary narcoleptic cases had a similar mechanism to that of the symptomatic cases, and he was unwilling to separate them. Clinically, he said, it was important to consider the actual condition of sleep which occurred. It was not true sleep, since patients were aware of what went on around them. There were transitional states between sleep and narcolepsy, and in certain cases emotion seemed to promote sleep; while cataplectic attacks might come on apart from emotional disturbances. He thought

that by broadening the conception of sleep in its relation to narcolepsy more light was thrown on the condition. Dr. Wilson then dealt with the relationship between narcolepsy and epilepsy. He remarked that the resemblances were much greater than the differences. The state of the patient in the fully established epileptic fit, with loss of consciousness and limbs in motion, was almost the "corresponding opposite" of the cataplectic, with consciousness retained and complete atonia in all muscles. There were a fair number of cases with narcolepsy and epilepsy in association, and while the symptoms were in striking contrast it might be that there was a similar physiological mechanism behind the two conditions. Dealing lastly with the possible pathogenesis of narcolepsy Dr. Wilson pointed out that the phenomena were largely inhibitory, and as in epilepsy many of the processes were inhibitory, so in narcolepsy these inhibitory effects were pushed a stage further. Pavlov's views on sleep showed that it consisted in cortical inhibition descending to the mid-brain, and it was possible to suppose that if the inhibition did not descend to the mid-brain the state of cataplexy might develop. He thought that light would be thrown on the problems of narcolepsy by consideration of the phenomena of cataplexy and atonia.

Dr. C. WOLSTEN-DROUGHT described the prominent features of four cases of narcolepsy which he had had under his care. He said that it was unusual for the cataplectic attacks to precede the attacks of sleep, and he emphasized the extreme atonicity which occurred during the attacks of cataplexy. He thought that narcolepsy was a symptom-complex comparable to, say, Parkinsonism, and we had yet to discover the nature of the lesion in the nervous system in cases of idiopathic narcolepsy.

Sir JAMES PURVES-STEWART said that in cataplexy, in narcolepsy, and in normal sleep there was this striking atonia. He referred to the state of hypersomnia which developed in patients with lesions round about the third ventricle, and he mentioned the fact that if the third ventricle was inflated with air then a period of peaceful sleep often developed. He said that the paroxysmal nature of the narcoleptic attacks had not yet been explained.

Dr. H. COHEN described some cases of narcolepsy he had seen during the last three years. One patient suffered from cataplexy on hearing a sudden noise; another boy with spastic diplegia fell to the ground on hearing a noise and then developed myoclonic movements, but was conscious the whole time. A third case, of a woman with cerebro-spinal syphilis, used to have epileptic attacks on hearing a noise. He had seen a similar gradation of symptoms in cases with attacks following uproarious laughter.

Dr. GORDON HOLMES mentioned two cases of narcolepsy. One showed an interesting feature in that nose bleeding, to which the patient was subject, stopped during the narcoleptic attack. Another case of cataplexy developed attacks when annoyed. A case of symptomatic narcolepsy, possibly due to some lesion in the region of the optic tract, had benefited from the administration of thyroid gland. He referred to a case in which cataplexy was brought on by sudden noise which had subsequently developed very marked epilepsy. Sleep had never been a prominent feature of this case. He disputed one of Dr. Wilson's statements with regard to sleep, stating that during the early stages he was convinced from personal experience that we were not fully unconscious. Dr. R. D. GILLESPIE related a case in which slight emotions, rather than severe ones, brought on cataplectic attacks. This patient had appeared to benefit from the administration of hyoscine.

#### HEALTH LESSONS FROM BERMUDA.

At a meeting of the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine, held at the Society's house on March 1st, Dr. J. GORDON THOMSON, vice-president, in the chair, Dr. ANDREW BALFOUR, director of the London School of Hygiene and Tropical Medicine, read a paper on health lessons from Bermuda.

Dr. Balfour pointed out that Bermuda was a small group of islands in the North Atlantic, with no geographical connexion with the West Indies. Its climate was sub-tropical, but owing to a large coloured population many

features and characteristics of tropical hygiene and sanitation were reproduced. Its isolated position had also perpetuated certain traits apparent among other communities, forced by similar circumstances to work out their own salvation. The islands consisted of acolian limestone, superimposed on a submarine mountain, and covered with a scanty red soil, free from clay. The limestone varied in consistency, but everywhere water readily percolated through it. There was no surface running water. The main island had an area of 9,000 acres, and its highest point was only 250 feet above sea level. The scenery was diverse—low hills and valleys with marine swamps and fresh-water marshes. The islands were well wooded with cedar or juniper, which influenced rainfall and protected against salt-spray from gales. The climate was mild and monotonous, but heavy rains and gales were common in early spring, and summer was hot and oppressive, the mild weather returning in September. Only a few of the 150 islands were inhabited. The population was over 20,000, of whom 9,000 were whites, the remainder coloured. The enervating climate had left traces on the white population, which was easy-going, with a tendency to procrastinate. The whites showed a mild "tropical anaemia," which was really a cutaneous ischaemia. Hookworm was absent, probably on account of the unfavourable soil; the inhabitants, however, were usually shod, which helped to account for the absence. Fifty years ago the chigger flea was common, but it had now disappeared; this had not been satisfactorily explained. Malaria also was absent, and anophelines had never gained a footing on the islands, although opportunities must have been frequent in the past for its introduction. The alkalinity of the waters might account for this, but the pH of Bermuda marshes had not yet been studied. Small fish (mullet), *Fundulus bermudae*, were common, and these kept down the species of mosquitos which were present (*Culex fatigans* and *Aedes* spp.). A balance had been struck between the fish and these mosquitos, but the fish and carnivorous arthropod larvae might have been more successful in exterminating anophelines. The recent introduction of malaria into Barbados indicated that Bermuda's "immunity" must not be viewed with complacency. Among the mosquitos present was the yellow fever vector *A. aegypti*. Numerous outbreaks of yellow fever (some of which, however, were probably really typhus) had been recorded in the past, although the disease was now absent. This might be due in part to the substitution of iron steamers for wooden sailing ships; but the fact that the disease never gained a permanent hold on the colony was probably more important. This might possibly be attributable to the unfavourable winter; moreover, the disease had also been stamped out in many old-time foci in America. It was likely that the long immunity from the disease depended chiefly on "chance." In Bermuda water was mostly stored in stone tanks, in which *Aedes* bred, and the introduction of fish was practised. The fish might introduce *B. coli* into the water, however, and, although harmless, this might falsify water examination results. Recent work indicated that the spirochaete of yellow fever might be identical with that of Weil's disease, and investigations in rats in Bermuda were suggested. The Bermudian was more or less immune to the bites of the salt marsh mosquitos, and this suggested another line of investigation. Dysentery was rare in Bermuda, probably because there was no running surface water, although flies were very common owing to the large number of horses kept on account of the tourist traffic. The flies, however, could transmit enteric fever, the second commonest disease there. It was uncommon among the troops, who had a piped water supply, a water-carried sewage system, and anti-fly measures, in addition to the usual triple vaccination. To rely on the vaccine alone for the protection of civilians was an unsound system which should not be the first line of defence; a satisfactory water supply was much more important. Tuberculosis was the commonest disease present. Bermuda was very thickly populated, but overcrowding was not common and slums were rare. The disease was rife among the coloured people because of closed windows, indiscriminate expectoration, and a bad milk supply. Inspection of school children was recommended as a preventive

measure for this and other diseases. The infant mortality rate was very high—about 160 per 1,000. The influx of tourists in recent years had caused people to flock to the towns; to neglect agriculture, and to rely on "canned goods" for food. This dietary apparently had had no ill effects on the inhabitants, but the empty tins provided breeding places for mosquitos and flies. Bermuda was full of lessons which, if learned and acted upon, would make it one of the most healthy places in the world.

Dr. G. C. Low compared the Bermuda of to-day with the West Indies of twenty years ago, and said that they were similar in many respects. Anopheles was absent from the water in Barbados (although he had shown that it could breed in that water). Other mosquitos were very common in water barrels, particularly *Culex*, the vector of *Filaria bancrofti*, and *Aedes*, the vector of yellow fever. There was a piped water supply, and although he had strongly advised precautionary measures at the time, nothing was done. Filariasis was rife, and in 1907 yellow fever broke out. Later, Dr. Balfour had suggested the provision of traps near the harbour to prevent the introduction of anophelines. Still nothing was done, and now malaria had arrived, and its extermination would be expensive. To prevent the possible introduction of malaria into Bermuda would be simple, but ignorance was still colossal. He had noted that in the West Indies yellow fever epidemics came in waves at intervals; Weil's disease, if present in rats, would appear sporadically.

Dr. FLETCHER emphasized the necessity for investigations into disease in countries where the disease did not exist, and cited the recent work on scarlet fever in the Dutch East Indies. The disease was absent there, and in children of 2 years the Dick test was positive. Yet as the age increased so did the immunity, and in adults the test was usually negative.

Dr. J. F. C. HASLAM considered that proper hygiene only followed a popular demand, and that the education of laymen was essential before this could be brought about. Each country, moreover, must specially design its own sanitary administration, not blindly copy that of the mother country.

Dr. H. H. SCOTT thought that anophelines must have been introduced, while malarial cases certainly had been imported in small numbers on occasion. Why had malaria not survived? He pointed out that yellow fever elsewhere, as, for example, in Jamaica, died out from time to time, although the vector remained present.

Dr. MANSION-BARR recalled a suggestion by Sir Patrick Manson that medical governorships would help to solve many of the important problems of the tropics. He emphasized the value of negative evidence throwing light on disease, citing the absence of yellow fever and typhus from many of the Pacific islands.

Dr. BALFOUR, in replying, showed that many difficulties had to be tackled before local prejudices and ignorance could be overcome. Compulsion from this country was difficult because many of the islands were self-governing. He thought that an appeal to the pride of the Empire which was so strongly developed in these people would help, together with adequate museum and similar education both at home and abroad.

### NEUROSES IN THE TROPICS.

THE Sections of Tropical Medicine, Psychiatry, Neurology, and Balneology of the Royal Society of Medicine combined on March 13th for a discussion on neuroses in the tropics. Dr. R. LANGDON-DOWNS presided.

Dr. H. B. DAY, opening, said that the subject was so wide that it might be considered under two headings: neuroses or psychoneuroses as seen (1) in native inhabitants, and (2) in European residents in tropical countries. The study of primitive races was a vast psychological subject. In the unsophisticated native hysteria was very prevalent, and emotionalism was exploited in tribal songs and war dances. That hysterical manifestations were amenable to suggestion was recognized by the peasantry in Egypt; whereas medical treatment was employed in ordinary illness, special religious ceremonies were prescribed for the hysterical patient. Turning to the European in a tropical

environment, Dr. Day instanced the strain to which he was subject owing to climatic conditions—the tension of an electrically charged atmosphere, the monotony of a tropical downpour. In this case of men taking appointments abroad the risk of breakdown was reduced by careful selection and apprenticeship, but these precautions were generally lacking in the case of the women who went with them, and for whom outside distractions were few and the scope of domestic interest restricted. The development of psychoneuroses was due to the failure of the individual to make mental adjustment to his environment. Persons whose moral control and education were not of a high order might sink to a low level, satisfying their desires at the expenso of their civilization. In others an unresolved mental conflict existed which might lead to a psychoneurosis. Of tropical diseases he mentioned two—malaria and pellagra—which produced not only psychoneuroses, but actual insanity. Pellagra, though more restricted in its geographical distribution, was the more important cause of nervous disorder; and it was estimated that 40 per cent. of the adults affected showed mental deterioration, with symptoms ranging from simple depression to confusional insanity terminating in dementia.

Lieut.-Colonel O. A. R. BERKELEY-HILL, I.M.S., sent a paper, which was read in his absence. He referred to the correspondence which appeared in the *British Medical Journal* in 1926 following a letter from the Bishop of Singapore on mental irritability and breakdown in the tropics. Eight replies were published, but no two correspondents agreed on the cause, and the diversity of explanations suggested indicated the hopeless ignorance which existed about a subject the importance of which could not be denied. Recognition by the laity that Europeans were liable to mental disorder in the tropics was shown by such terms as "Punjab head," "West Coast head," and the German "Tropenkoller." The Duke of Wellington deplored the irritability of many of his officers in India. Novels dealing with life in the tropics abounded in references to mental disorder among Europeans—those by Kipling, Conrad, Seton Merriman, for example. Europeans living in the tropics appeared to be prone to a neurotic syndrome, the central symptom of which was a state of hypertension manifested in general irritability or morbid anxiety. He thought there was some justification for the assumption that the mental disorder of Europeans in the tropics was an anxiety neurosis. Among causes he mentioned sexual abstinence, frequently inevitable, even among married men, and followed sometimes by resort to alcohol as an indirect result; another cause was coitus interruptus, lamentably common among Europeans living in tropical countries, and leading to many nervous and other ill results in both men and women. Little was known about temperature, perhaps the most formidable of tropical conditions; but many facts went to suggest that an average temperature between 60° and 70° F. was better than one which averaged over 70° F. It was evident, therefore, that Europeans in tropical countries, unless they lived at high altitudes, were under a perpetual disability. Climate played an important, though unassigned, part in mental well-being.

Dr. HUGH STANNUS said that the correspondence in the *British Medical Journal* had laid the blame for disturbance of mental health in the tropics upon every conceivable component of the tropical environment. He himself believed that the condition commonly seen in the tropics was a neurasthenia—a neurosis consisting in faulty response by over-action to the difficulties which life offered, the symptoms being abnormal liability to fatigue and irritability. This faulty response was due essentially to the introduction of fear into the mind—whether fear of physical hurt, or fear as a component of worry, anxiety, apprehension, and disappointment. In the neurasthenic in the tropics harmful emotional and physical stimuli might be seen severally at work. Cases of neurasthenia might be observed which did not differ in their causation from cases in this country. There was also, however, the man exiled from home, separated from his family, perhaps in financial straits, lonely or lacking congenial society, disappointed in promotion, unable to escape from monotony, living amidst a native population who caused him annoyance

because he had never troubled to understand their language or their psychology, beset all day by sodden heat and the incessant attention of insects, and driven to bed only to be kept awake by the reiterated cry of the brain-fever bird or a chorus of frogs. Such a man was always suffering from a summation of multiple, minor, defence-inducing noxious stimuli. Here, in this emotional and physical unrest, lay the cause of tropical neurasthenia.

Mr. A. F. MacCALLAN said that he was one of the first to write to the *British Medical Journal* after the Bishop of Singapore's letter to point out the extraordinary strain on persons in the tropics as a consequence of suffering from slight errors of refraction which elsewhere would be almost negligible. With regard to neurasthenia, there was often a physical basis for this in some septic focus in the oral cavity or alimentary canal, and its existence could nearly always be detected by an ophthalmic surgeon on an examination of the eyes.

Dr. J. F. C. HASLAM suggested that not only the diversity in the *British Medical Journal* correspondence but also the present discussion went to endorse the contention of Dr. Stannus—that underlying the whole of this condition of tropical neurasthenia were very many noxious stimuli. The speaker, however, was inclined to place rather more weight on pure climatic conditions than Dr. Stannus had done. In industries involving exposure to high temperature and humidity some recent observations by the Industrial Fatigue Research Board went to show that as soon as a temperature of over 75° F. was reached there was a falling off both in efficiency and output. Temperature and humidity were undoubted factors, when they passed beyond the points customarily experienced in temperate climates, in exercising a harmful effect. In Australia they were accustomed to speak of a "kitchen neurosis," a condition affecting women who spent a great deal of time in the kitchen, which was, of course, the hottest part of the house.

Dr. HALLIDAY SUTHERLAND said that it was well for practitioners in this country to study this subject in view of the large number of men who during the war went into the tropics and acquired tropical diseases for which they still needed occasional treatment. He mentioned the case of a man suffering from extraordinary delusions who, during a stay in Persia, had had malaria, paratyphoid, typhoid, dengue, and sandfly fevers. His mental trouble had begun eighteen months ago. Dr. Sutherland had concluded that this patient was the victim of chronic malarial poisoning; quinine treatment had begun and the man was now resolving his own delusions.

Dr. MILAIS CULPIN spoke of the conditions in tropical or subtropical Queensland; of which he had experience, and contrasted them to their great advantage with the conditions in Shanghai, which was notoriously a "nervy" place. This "nerviness" might be due to the tropical disorders which were rife in Shanghai, and from which Australia was free, but he thought it much more likely to be caused by the air of unsettlement about the whole place. Nobody went to Shanghai with the idea of making it his permanent home. Neuroses were extremely common there, and were not confined to Europeans.

Sir ROBERT ARMSTRONG-JONES said that he had had some experience of mental cases in Tunis and at St. Peter's Asylum, Marseilles, where confirmed psychiatric cases were received from equatorial Africa. His own view was that when dealing with an unsophisticated and incomplete civilization the psychasthenic or neurasthenic was not found. He was struck by the fact that among many African mental cases he had not seen the highly evolutionized forms of disorder; the conditions found were simply due to failure in development.

### THE VALUE OF MARINE HEALTH RESORTS.

A discussion on the value of marine health resorts, with special reference to children, was held at a meeting of the Section of Balneology and Climatology of the Royal Society of Medicine on March 8th, with Dr. L. C. E. CALTHROP in the chair.

Dr. PORTERUE FOX recalled a remark by Sir Hermann Weber that no country could compete with Great Britain

in the variety and value of its marine health resorts. Weber had also expressed surprise that although England was the first country to establish seaside hospitals and sanatoriums, it had done comparatively little to develop facilities for treatment on the coast. The foundation of the Royal Sea-bathing Infirmary at Margate in 1791 marked the opening of a new epoch in physical medicine, but it was not until the latter half of the nineteenth century that the remarkable popular movement seawards began. A philosophical explanation of the benefit of the sea, to which the speaker was attracted, was given by the Frenchman Quinton, who said that the sea was the original medium of life, and that from the sea came the first living soul. The marine climates of these islands presented an interesting study. It was commonly said of France that there were three seas, and this was true for the coast of the British Islands. The western sea, with its soft Atlantic airs, was to be recommended for the winter and spring; the strong eastern seas were for summer and autumn, and the south coast was for all seasons. A useful generalization, subject to many exceptions, was that the east was for the young and the west for the old, but the western climate was not always relaxing and sedative. Along the indented coast there were health resorts covering every conceivable variety of aspect, shelter, and soil, and a number of purely local climates apart from the three-fold division indicated; these secondary characteristics of climates determined very often their value for invalids. Only at the seaside could so many forms of energy play upon the skin and respiratory membrane. Passing to the dangers of sea bathing, Dr. Fox said that the duration of the bathe, even as measured in seconds, might easily turn a benefit into a peril. A bathe at 65° was the coolest that should be recommended for medical purposes, and the temperature of our seas in summer was, on the eastern coast, 61° to 68°, and on the western from 5° to 10° higher. Apart from the danger that arose from chill, there was a danger of exciting or aggravating acute or febrile disease; probably the explanation was that where the bathe was badly borne there was some congestive process already at work which was aggravated thus. Another drawback was what used to be called "marine fever"—a transient disturbance marked by sleeplessness and slight pyrexia after bathing. In conclusion Dr. Fox indicated certain tasks which might properly be undertaken by the Section in obtaining information and comparing records in connexion with marine therapeutics.

Dr. FRANK LEWIS (Folkestone) dealt with some special considerations of marine climates, such as moisture-laden winds, pointing out that although the circulation of fresh air was an advantage, the force of wind was coincident with a high death rate from phthisis wherever a community more or less tainted with tuberculosis of the lungs was exposed to it. The most important factor was sunlight. As for the effect of seaside resorts on children, the consensus of opinion from heads of schools was that the resistance to infectious disease was increased. Epidemics of zymotic disease had few terrors for those who lived at the seaside. The most bracing district in Britain was the Isle of Thanet, where the sea winds were drier than elsewhere. Sea bathing was an excellent pastime for the healthy, but was not to be recommended for the ill; as a factor in marine resort treatment it was of minor importance.

Dr. W. G. WILLOUGHBY (Eastbourne) said that he was sometimes asked by inland medical practitioners for the mean annual temperature of Eastbourne; such a figure would be practically worthless. What was required was the mean of the daily maximum and of the daily minimum. Another question frequently asked was the amount of the total rainfall; this was important in some degree, but not nearly so important as the number of rainy days. He had found one place mentioned in the Meteorological Office reports where the annual rainfall in any one year was 80 per cent. above the average rainfall of the country, but the number of rainy days was only 15 per cent. higher. He had seen much damage done by sea bathing; its value depended very much on the individual. To those who indulged in it regularly there came a day, probably in the late autumn, when slight malaise followed the usual bathe;

that was the time to stop. A medical officer in charge of the examination of school children at Eastbourne, who had had previous experience in rural and urban districts, had stated that children in rural districts were the least healthy, while those of Birmingham and Eastbourne who lived in comparable homes were about equally so. This suggested that the factors of good food, clothing, and housing were more important than climate, but the seaside had a special value in respect of change of air.

Dr. COLLIS HALLOWES (Torquay) said that there was probably more iodine in sea air, and he had been struck by the number of children suffering from defective thyroid function who did extremely well at Torquay. With regard to elderly invalids, this town was recognized as being good for cases of high blood pressure. After surgical operations, also, convalescents benefited from its equable climate, warm sunshine, and freedom from extremes. Dr. Hallowes also spoke of the value of Devonshire resorts in the rheumatic group of diseases.

Dr. G. R. BRUCE (Hastings) said that there were two fairly distinct climates at Hastings; one on the seashore, where there was protection from the east by cliffs, was definitely mild, and the other to the north, where there was a hinterland of rising ground to 300 or 400 feet, was definitely tonic, and much cooler than nearer the sea. His experience was that children suffering from catarrhal conditions, and debilitated children generally, did well at Hastings. He thought there was a field for the development of marine resorts by the provision of regulated sun treatment in solariums for people, especially sedentary business people, who were "run down" and out of sorts, and who at present indulged in haphazard sunshine treatment.

Dr. A. F. STREET (Westgate-on-Sea) could not ascribe the immunity of seaside resorts from zymotic diseases to any particular factor, but its existence was undoubted. Referring to a remark by Dr. Fox that some children were apt to be upset by residence at the sea, he said that this was only in cases which had been badly mismanaged. After forty years at a seaside resort he had yet to find any rheumatic affection result from a visit.

Dr. W. S. CAMPBELL (Sidmouth) said that he had practised on the coast of Northumberland and at Sidmouth; in spite of the climates, winds, temperatures, and country being so diverse, the effect upon children in the two places was identical, except that in winter children were not benefited by the Northumbrian coast. He thought that heliotherapy was the principal factor in the value of seaside resorts.

Dr. W. G. SUTCLIFFE (Margate) mentioned the dry and bracing winter of Margate and the excellence of its climate for the treatment of surgical tuberculosis. The increase in metabolic activity, judiciously controlled, was undoubtedly the prime factor in promoting the tissue healing which was observed in these cases. Dr. Sutcliffe's photographs of children reinforced this testimony to the value of Thanet.

Dr. OCTAVIA WILBERFORCE (Brighton) said that children with ordinary childish complaints recovered wonderfully at Brighton, but with heart trouble they did not prosper so well. She found that convalescent child visitors to Brighton showed a weekly gain of 8 oz., whereas resident children who had been ill gained anything from 9 to 16 oz. a week. She emphasized a point which applied to all other resorts also—namely, that those who lived permanently at Brighton needed a change as much as those who lived inland.

## SURGICAL TREATMENT OF CHRONIC GASTRIC ULCER.

At a meeting of the Devon and Exeter Medico-Chirurgical Society on February 23rd, the president, Mr. A. L. CANDLER, in the chair, Dr. S. C. SHAW (Barnstaple) opened a discussion on the surgical treatment of chronic gastric ulcer associated with severe haemorrhage.

Dr. Shaw suggested the following classification as convenient in view of the discussion he wished to promote:

*Type 1.*—Cases with small and repeated haemorrhages at short intervals.

*Type 2.*—Cases with isolated haemorrhages small in amount and with a long period between them.

*Type 3.*—Sudden haemorrhages so profuse as to be frequently heralded by fainting.

Dr. Shaw said that in the first type the patient did not appear to be in any immediate danger, and if left untreated surgically would probably survive for many years, with alternating periods of quiescence and active haemorrhage. There was, however, risk in delaying surgical measures to a period when debility with profound anaemia was established, and in illustration the case was recounted of a man, aged 54, who had been thus reduced by chronic haemorrhage. Although gastro-jejunostomy offered no difficulties at the time, convalescence was delayed by the abdominal wound failing to close. This necessitated re-suturing, which again gave way partially, so that perfect healing was not established until nine weeks from the primary operation. The ultimate effect of the anastomosis proved to be good. Dr. Shaw mentioned two similar cases where the abdominal wound made very slow repair without any trace of sepsis. As a further instance of Type 1 and the danger of delay he described the case of a middle-aged man in whom a diagnosis of gastric ulcer had been established for some considerable time, and who had been admitted to hospital with a view to operation on three occasions and refused at the last minute. On the third admission his condition was so grave that a preliminary transfusion was considered necessary. The 1½ pints of blood transfused had an immediate improving effect, but unfortunately he regained a false sense of security, and, as a result, died four weeks later from heart failure consequent upon his exhausted and anaemic condition. Dr. Shaw reported the case of a woman, aged 53, where there was delay in operating, and where the ulcer was eventually found to show characteristics suggestive of carcinoma. Partial gastrectomy was performed, and ten months later the woman was apparently well and had gained considerably in weight. Dr. Shaw said that four conclusions could be drawn from the treatment of Type 1 cases: (1) that gastro-enterostomy gave cessation of haemorrhage; (2) that delay was dangerous in that the patient became too weak to withstand the actual operation; (3) that delay endangered the recuperative power necessary for the healing of the wound; (4) that the danger of overlooking a carcinoma until such time as it became inoperable must also be borne in mind. To illustrate Type 2—"the small infrequent haemorrhages"—Dr. Shaw instanced the case of a man, aged 35, first seen five years ago with slight haematemesis. There was a vague history of epigastric pain and discomfort after food. The subsequent history showed recurrence of the pain, but there was no evidence of vomited blood or melaena until six weeks ago. The barium meal showed a hypertonic stomach, very active peristalsis, rapid emptying, but no definite sign of ulcer. The symptoms responded to medical treatment, and the man had returned to work. Dr. Shaw considered that this type of case occurred more frequently in younger subjects aged 25 to 35, and, even granted that the diagnosis of ulcer was established, he did not advocate the ready adoption of surgical measures in these patients in the absence of evidence suggesting pyloric obstruction. Untoward sequelae, such as jejunal ulceration, were likely to occur among these cases. Dr. Shaw then spoke of the sudden large haemorrhage of Type 3, of the urgent problem, and of the heavy mortality presented by this class of case, often duodenal in origin. Ulceration might occur into some large vessel such as the splenic artery, the coronary arteries, or the gastro-duodenal. Dr. Shaw advocated operation without delay in these cases, having regard to the danger of recurrence of haemorrhage. The ideal operation was that which removed the ulcer or controlled the source of haemorrhage by ligation, and was followed by gastro-enterostomy. The extent of this procedure could only be determined in the individual case at the time of operation, and gastro-enterostomy might alone be possible.

Dr. C. H. MILLER said that divergence of opinion between the physician and surgeon was more apparent than real on the treatment of gastric haemorrhage; many physicians welcomed an operation in that it shortened the period of treatment. A difficult problem often arose in

one of these severe cases of haemorrhage, owing to the patient being too ill for routine examination, and then it was necessary to resort to the history for a decision. Dr. Miller agreed in counselling operation in cases of chronic ulcer; the gravest haemorrhages were to be feared in the region of the lesser curvature. He showed a drawing illustrating a chronic ulcer which had eroded the splenic vessels and established a dissecting aneurysm. In Dr. Miller's experience the acute cases of ulcer were more liable to bleed than were the chronic, but at the same time he advocated medicinal treatment for acute cases where the indications were moderately safe, and advised as a broad rule that the chronic cases should be treated surgically. Fainting and sudden collapse were important signs, pointing to erosion of some large vessel. Dr. Miller finally drew attention to cases of haematemesis in young girls where fainting occurred before the haematemesis. He said that these patients recovered under the care of the physician, but died if surgically treated.

Mr. NORMAN LOCK mentioned eight cases of severe haemorrhage observed in recent years; all but one had ended fatally. Four had been treated medically, and an equal number had come to operation. He agreed with Dr. Miller as to the infrequency of haemorrhage in the chronic ulcer. He had formed a favourable opinion of gastro-jejunostomy alone from his own experience in operating on these cases. He welcomed transfusion as a present help in these sudden severe haemorrhages.

Dr. COREY reported a favourable experience of the intensive alkali treatment in gastric ulcer, the results of which now made him very unwilling to advise a gastro-enterostomy. Dr. R. V. SOLLY discussed the question of transfusion and the advisability of introducing a small quantity at a time; large amounts might actually increase the liability to haemorrhage. Dr. Solly also suggested the intravenous injection of calcium chloride when a doctor was not at hand.

Dr. W. GORDON spoke of the trying situation which had to be immediately faced in the case of a patient suffering from sudden gushes of blood from the stomach: where was the haemorrhage, should a surgeon be called in, or should the treatment be medical? The surgeon might say that an operation offered more risk than leaving the patient alone. In this case Dr. Gordon said that the immediate indication was morphine followed by haemoplastin, calcium chloride or lactate, or adrenalin chloride. In acute cases he agreed that it was best, as a rule, not to operate, but in the chronic cases—especially chronic ulcer occurring in older folk—more especially duodenal, he advised operation. The intensive alkaline treatment was a modification rather than a new form; a man at present under his care appeared to be doing well on alkalis.

Dr. F. A. ROPER was also favourably impressed with the modified treatment with alkalis. As regards the cases of severe haemorrhage, his experience in the medical wards was that the majority of those considered inoperable on account of their general condition recovered under medical treatment. Dr. Roper also gave his personal experience of transfusion, and mentioned three recent cases. On one, a big robust man, transfusion had no effect, death occurring in thirty-six hours, while in the two others the immediate effect was striking.

Dr. J. A. W. PEREIRA GRAY recalled five cases of severe haemorrhage occurring in his practice during the past twenty-five years; all the patients had refused to have an operation performed, were treated at home, and made a good recovery. He had found cocaine and adrenaline valuable when given by the mouth during the stage of haemorrhage, and magnesium sulphate in small doses subsequently.

The PRESIDENT considered that the most important advance in the treatment of these cases was blood transfusion. He had been associated with Dr. Roper in the case of the patient with the low haemoglobin count. This man had refused operation, but had been able to eat ordinary food when he left hospital. Mr. Candler agreed that excision should be performed wherever possible, but up to the present the results were not good for the excision of the acute bleeding ulcer.

## RADIUM IN CANCER OF THE BREAST AND TONGUE.

At a meeting of the Brighton and Sussex Medico-Chirurgical Society on March 1st, the president, Dr. DONALD HALL, in the chair, Mr. DUNCAN C. L. FITZWILLIAMS gave a lecture entitled "The role of radium in treatment of cancer of the breast and tongue."

Mr. Fitzwilliams began by recalling the birth of modern surgery, its extensive growth at first and its slower progress subsequently as fewer fields were left for exploration. He thought that the time would come when the whole of the body would have been explored by surgical means; technique would have reached its highest, and surgery, as known now, would be on the wane. Its nature would alter, and perhaps a hundred years hence there would be contempt of the doings of to-day. One of the present changes was the replacement of surgery by radium in areas where it could be applied. In the tongue radium had largely replaced the knife among surgeons who understood its use.

Mr. Fitzwilliams mentioned the several methods of applying radium, and particularly the insertion of seeds of glass containing radium emanations. These seeds were planted in the tissues and left there; the radium emanations diminished gradually and the glass capsules remained. One drawback of this method was that if used in a septic cavity such as the mouth sepsis might supervene, and the capsule could not be found in the oedematous tissue. He had seen an instance of this in the case of a tonsillar growth. A better method was the insertion of metal capsules containing emanations with a fine piece of silk attached, so that they could be withdrawn after a certain time. He described an instrument after the manner of a trocar and cannula for the introduction of these seeds. This method of applying radium was rather new, and it was too soon to say whether it would hold its own, but, he added, superficial growths disappeared as if by magic when treated in this way. He described the use of needles containing radium; these needles, of varying lengths, were composed of platinum 0.5 mm. thick, so as to screen off injurious rays from the tissues. They should contain 0.2 to 0.5 mg. of radium, and the most useful length, he thought, was about one to two inches. He described their employment fully, and said that they should be left in place for a week or ten days. He then discussed tubes containing about 50 mg. of the metal heavily screened; these were good in such cases as carcinoma of the cervix. An efficient method of treating cancer was to place large doses in the centre of the growth where the cells were degenerating and harmless. It was much better to surround the growth with radium needles so as to deal with the actively growing edge. The last method described of using radium was by tubes or plaques, either of the metal itself or radiations, which were placed upon the skin. He said he had never obtained good results from this method in large growths, but it was a very good way of dealing with small superficial growths, such as rodent ulcers and epitheliomas of the lips. In dealing with the breast it was pointed out that extrathoracic carcinoma alone could be dealt with; if the cancer cells had already gained the interior of the chest, the patient would probably die owing to internal metastases, however widely the original growth might be removed. In the early stages of primary carcinoma of the breast the knife was far superior to radium; only in atrophic cases, cases unsuitable for operation, or in encephaloid cases was radium recommended. The great function of radium lay in dealing with the external metastases; and these could be treated with the certainty of cure. Illustrative cases were given. In the tongue the disease superficially was local, but penetrated very deeply. It was the failure to realize this depth of penetration which was the cause of local recurrence after operation. Seeds or needles would cause the growth in the tongue to disappear, but left a very suspicious hardness behind. Different methods of treatment were illustrated. In the glands in the neck block dissection combined with the use of radium was recommended as the best treatment. Mr. Fitzwilliams strongly recommended the use of lead in combination with radium.

## MEDICO-LEGAL ASPECTS OF CRIMINAL ABORTION.

THE position of the medical practitioner in cases of criminal abortion was considered by Dr. G. ROCHE LYNCH, senior official analyst to the Home Office, in the course of a lecture delivered on March 7th at the Royal Institute of Public Health, with Mr. Justice HUMPHREYS in the chair. It was probable, Dr. Roche Lynch said, that at the present time criminal abortion was being practised to a greater extent than ever before in Great Britain, on the Continent, and in America, and the subject was therefore one of the most pressing problems with which forensic medicine had to deal. Criminal abortion was a felony in this country, and it was the duty of the Crown to prosecute persons suspected of this crime and persons who were accessory to the fact. It was the intention that constituted the crime, and it was not necessary that abortion should take place. To the medical man abortion and criminal abortion were two entirely different things. The former was only practised by reputable obstetricians where it was necessary to save the life of the mother. The decision to terminate pregnancy was a question of medical opinion, and a golden rule among doctors was never to empty the uterus until a second opinion in agreement with the first had been obtained—a rule to the interest of patient and doctor alike.

Certain obstetricians during recent years appeared to have practised abortion in cases where the mother's convenience only, and not her life, was at stake. Sir Archibald Bodkin had said that whereas abortion had been practised in former years on unmarried women, since the war the vast majority of cases had been among married women of the poorer classes living with their husbands in towns. Dr. Roche Lynch said that what usually happened was that the unfortunate woman, having missed one or two periods, took drugs. She often gave up the treatment either because it failed or because it made her feel ill. By this time the foetus was nearing the third month of gestation, and usually some mechanical interference was attempted. As a result of this interference the woman often became ill, and it was then that the doctor was called in.

What were the doctor's duties to the State in regard to giving information? Professional secrecy was a jealously guarded privilege, but it had been subjected to criticism by judges at times. Partly as a result of an utterance of Mr. Justice AVORY, the Royal College of Physicians, in 1916, considered the question with great care, and had taken the opinion of learned counsel. [The subsequent findings of the College, together with a full account of the circumstances in which the question arose, were published in these columns on February 5th, 1916, at p. 206.] Continuing, Dr. Roche Lynch said that the opinion had been expressed by Sir William WILCOX that where there was conclusive objective evidence of criminal interference—for example, wounds on the cervix—the medical practitioner who took no steps at all was unwisely inflicting upon himself a grave responsibility which might lead to serious trouble; where there was conclusive objective evidence of criminal interference, quite irrespective of any statement made by the patient, there was no doubt that the duty rested on the medical practitioner of informing the legal authority. Dr. Roche Lynch added that he had heard judges say that should an action be brought against a doctor for betrayal of such confidence no jury would convict. Nevertheless, to obtain a verdict in his favour the doctor would be put to considerable expense.

Mr. Justice HUMPHREYS said that there could be no question that criminal abortion was very rife in this country, even more so than it was many years ago. There was one point in regard to the matter in which a mistake was being made by some medical men and some lawyers. Anyone who wished to abolish criminal abortion should remember that abortion and birth control were two totally different things. The first was highly criminal, while the practice of birth control might be desirable or undesirable, but at least it was not criminal.

## ADDISON'S DISEASE.

At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland on February 24th, the president, Dr. G. E. NESMITH, in the chair, Dr. L. ABRAHAMSON read a paper based on three cases of Addison's disease.

Dr. Abrahamson gave the following clinical details.

The first patient was a lad, aged 18, who developed slaty pigmentation of the skin, which became darker and more widespread, but was unaccompanied, for sixteen months, by any other symptoms. During this time the patient played games and was of normal physical strength. The systolic blood pressure was 140 mm. The mucous membranes were clear. Vomiting then set in, the mouth and tongue became diffusely pigmented, weakness developed and progressed to prostration, the systolic pressure sank to 40 mm., and death ensued one month later.

The second case was that of a woman, aged 27, who complained of weakness, anorexia, and loss of weight. She had brownish-black pigmentation on the backs of the hands and on the neck and face, with a streak on each lip; the systolic blood pressure was 70 mm. Her symptoms had followed the birth of a child. After a time the pressure sank to 60 mm., faintness and vomiting set in, and weakness became marked. Spots of pigmentation appeared on the mucous membrane of the mouth and tongue. The pressure dropped to 40 mm. systolic, and death followed.

The third case was that of a woman, aged 32, who developed, shortly after the birth of a child, weakness, faintness, and giddiness. With these symptoms there had appeared pigmentation of the skin, and attacks of vomiting, breathlessness, and palpitation. She was admitted to Mercer's Hospital in a grave condition, and eight days later she died. Her systolic pressure on admission was 60 mm., and before death it registered 40 mm. Pigmentation was practically universal, and there were streaks in the mouth. Vomiting, faintness, and prostration were marked. A necropsy showed advanced tuberculosis of the suprarenal glands, with a tuberculous nodule in one lung, and brown atrophy of the heart.

Dr. Abrahamson discussed the immunity of the first patient for sixteen months from the symptoms typical of Addison's disease. He suggested that this and the raised blood pressure were explicable on the assumption that the condition was for a time, wholly or mainly unilateral, and that the supervention of typical symptoms was due to the appearance of acute miliary tuberculosis in the healthier suprarenal. The interest of the second case lay in the fact that the only definite improvement during the course of the illness followed the application of radium, which was applied over the front and back of the trunk (suprarenal areas) and over the spleen.

Dr. T. G. MOORHEAD said that at first he had doubted whether the lad had Addison's disease, owing to the fact that the pigmentation looked more like diffuse sunburn than like the characteristic bronzing. Furthermore, it was not more marked on the nipples and axillae than elsewhere, and there was no involvement of the mucous membranes. The patient had, moreover, a blood pressure unusually high for his age. Dr. Moorhead now thought that this high blood pressure was perhaps due to stimulation of the adrenals in the early stages of the disease. He referred also to the frequency of severe and persistent lumbar pain as an early symptom of Addison's disease, since it occurred before the development of pigmentation and other symptoms.

Dr. A. R. PARSONS, referring also to the case of this lad, said that he would have been disposed to suspect a tuberculous lesion in some part of the body. He mentioned the case of a woman, aged 20, who had been admitted to hospital complaining of uncontrollable vomiting, and who had died; tuberculous disease of both suprarenal capsules had died; until then he had never seen a case of Addison's disease without pigmentation of the skin. Cases in which there was no pigmentation usually ran a rapid course, the patients dying within twelve months.

Dr. M. J. NOLAN asked if Dr. Abrahamson had found any alteration in the urine in his cases, and said that in one of his own cases there had been haematoporphyria. He mentioned a case of asthma in which asthmolysin had been used, and large patches of Addisonian colour appeared; on stopping the remedy the discoloration disappeared. Dr. ABRAHAMSON, in reply, said that the uric acid in all his cases had been normal to ordinary tests, and referred to two cases of cure of Addison's disease, quoted by Pybus, by grafting of the suprarenal.

## Rebichus.

### SURGICAL TREATMENT OF MALIGNANT DISEASE.

THERE is something almost overwhelming in the idea that a man should be found in these days brave enough to take the whole field of cancer surgery for his task. It is only one who, like Sir HOLBURN WARING, can command immense clinical resources such as those of St. Bartholomew's Hospital who could properly set out to teach the professional world what his experience has taught him. What these resources are can be clearly indicated by the mention of 748 cases of gastric, 500 cases of lingual, 1,523 of mammary, and 51 of uterine cancer in the twenty-year period quoted.

At first sight it is not quite obvious exactly to what audience this work, *The Surgical Treatment of Malignant Disease*,<sup>1</sup> is addressed. The specialists will perhaps think it best suited to the general surgeon. The general surgeon, on the other hand, may conclude that the specialist will find in it just the amount of information about the wider field that may suffice him; for the pages containing the letterpress number no more than 667, and a very considerable portion of these is devoted to illustrations, some of them inserted twice and one three times. No trouble, in fact, has been spared to make the book easy to read, though the regional arrangement of the chapters has the disadvantage, which extends to the index, of not bringing before the reader at once all the information available about such a subject, say, as "sarcoma of bone."

To review a book like this helpfully or constructively would require knowledge and courage like the author's. It must suffice to speak of the contents in general terms, and to record a few comments that are suggested by reading the sections. In the first place, almost every section ends with a statement of the author's experience of radium and irradiation in treatment, supplemented by a summary of that published by others. It seems that on the whole his impression of results is but little more favourable than that of the generality of surgeons a few years ago. This is rather unexpected in view of the results obtained at the Radium Institutes of Paris and elsewhere, not least at Sir Holburn Waring's own hospital. It is but right to say that the quotations from other writers offer a very useful and valuable summary of irradiation results.

The chapter dealing with cancer of the tongue may be taken as representative of the remaining forty-seven. Although the intention to deal with pathology is disavowed, this cannot, of course, be excluded. Clinical aspects, incidence, and diagnosis are taken in turn; there is then a brief statement of the principles of operative treatment, followed by a discussion of the considerations proper to feasibility and extent of operation. After a page about anaesthesia, the actual operations are described much in the form made familiar by the author's *Manual of Operative Surgery*, but expanded and with some additional figures to elucidate the probable lymphatic involvement. The pictures to illustrate "block dissection," unless studied in conjunction with a short paragraph ten pages back, hardly display to the full what is now meant by that term. This section, like the rest, concludes with a list of references to recent literature, a feature that will prove a most useful part of the book, especially as in many cases a digest of the matter is incorporated in the text. In regard to cancer of the oesophagus no way of escape from the prevailing gloom is indicated. Under "Stomach" it is interesting to find that the author has operated on several cases of perforation of a malignant ulcer; the published cases, as he mentions, are few. The figure on page 78 is a good one of gastrectomy for ulcer, but not adequate, perhaps, for cancer. The sections on malignant disease of the small intestine are interesting, of course, because of the rarity of the occurrence of cancer in this site; and they should prove useful, in estimating prognosis, to the average surgeon meeting his solitary case.

<sup>1</sup> *The Surgical Treatment of Malignant Disease*. By Sir Holburn Waring, M.S., M.B., B.Sc. (Lond.), F.R.C.S. Oxford Medical Publications. London: Milford, Oxford University Press. 1928. (Cr. 4to, pp. xx + 667; 277 figures, 18 plates. 50s. net.)

The discussion of cancer of the rectum reflects current opinions. The difficulties, such as avoidance of tear or wound of the bowel during the perineal operation, are hardly given enough prominence. Here it may be mentioned that the book does not embody the author's experience and advice as to the management of difficulties in after-treatment, which is a pity, since it is in the cases that, unaccountably or explicable, do not "go right" that guidance is sought by the less experienced. It is to be noted that in treating malignant disease of the testicle, operation extending no further than the internal ring is recommended; the theoretically complete operation is described, but "sufficient cases, however, are not yet on record to justify the general recommendation of this method." The suprapubic route is advised for removal of carcinoma of the prostate, but an abdominal incision "two to three inches" in length would not suffice for surgeons less skilled. In speaking of cancer of the cervix uteri the author says that a biopsy ought not to be necessary, and is to be deprecated as likely "to expedite the occurrence of metastases." It is to be noted that he apparently considers Broder's classification of malignancy of value, and in this context relies upon it for an estimate of the likelihood of glandular infection: must not the value be mainly associated with a biopsy? Cholecysto-gastrostomy (p. 451) is recommended, or as an alternative cholecysto-jejunostomy, though on page 460 we are left uncertain whether cholecysto-duodenostomy is not, in the author's opinion, the operation of choice. It is encouraging to learn that he has not had an operative death from removal of the spleen for malignant disease. For those cases of tumour of the hypophysis in which the main mass is above the fossa he has found the antero-lateral cranial route the best, but he mentions Sargent as preferring the frontal. On page 521 it is stated that a malignant growth commencing in the ganglion cells of the medulla of the suprarenal has the usual characteristics of a melano-carcinoma, and the reader is referred to Chapter 16 (hypernephromata); but the subject does not seem to be further elucidated. In dealing with sarcomata of the bones of the upper extremity Sir Holburn Waring does not give any decided personal advice as to the propriety of amputation, local removal, or reliance on non-operative methods. In the discussion of operations on tumours of the lungs the value of preliminary artificial pneumothorax is not made quite apparent, as the anaesthetist is told to increase the intrathoracic pneumatic pressure before the surgeon incises the pleura.

In reading this, or any, book on malignant disease, as in reflecting on cases, it is hard to relinquish the hope that some practical means may be found of reaching cancer cells wherever they may exist throughout the body—either to kill them by extraneous means or to awaken protective forces surely capable of evolution by the tissues. It is with regret, therefore, that we learn that the experience of St. Bartholomew's Hospital with Blair Bell's method has not confirmed the results he himself has demonstrated.

Sir Holburn Waring is to be congratulated on the energy and industry which, amid so much exacting public work, has enabled him to add this remarkable book to his achievements.

### PEDIATRICS.

THE basic idea of prevention, as has often been said, is gradually creeping its way into many branches of medicine, and while its presence had been obvious for some time in many small monographs on various aspects of diseases of children, no author had so far attempted a large textbook based fundamentally on this idea until *The Modern Practice of Pediatrics*<sup>2</sup> by Dr. WILLIAM PALMER LUCAS made its recent appearance. This volume is not by any means a "popular" exposition of elementary child welfare principles, but covers the orthodox field of pediatrics in a thorough manner; and the author has succeeded in demonstrating how even the most technical and intricate problems of the research laboratory and the most complicated clinical aspects of the subject are related to the

<sup>2</sup> *The Modern Practice of Pediatrics*. By William Palmer Lucas, M.D., LL.D. London: J. and A. Churchill. 1927. (Roy. 8vo, pp. x + 563; 125 figures. 30s. net.)

prevention of disease. The book is divided into two parts, the one dealing with infancy and the other with childhood. In the former the preventive idea is well developed in the care bestowed on the pre-natal period and the physiology and pathology of the infant. The latest work on nutrition is then taken up and discussed at some length, so that after chapters dealing with metabolism, vitamins, integumentary requirements, the problems of the child are approached on thoroughly modern lines. Disorders are considered in the modern spirit, and even if the terminology (as always in this department of diseases of infancy) is unsatisfactory, the author makes it quite clear what he means by the terms he employs. With chapters on certain special disorders such as congenital pyloric stenosis, rickets, tetany, and scurvy, for example, the first part of the book ends. The disorders of childhood are again dealt with from the preventive standpoint. From a discussion of normal growth and nutrition, the subjects of malnutrition and digestive disturbances follow naturally, and the various systems are then taken up in turn. A chapter on mental problems is especially good, and a short section on accidents is an unusual but welcome addition in works of this character. A final chapter on therapeutic and diagnostic procedures contains a very large amount of practical advice. At the end of each chapter a very full bibliography is given under the modest heading of "reference readings," and the list of authors shows Dr. Palmer to be well acquainted with the latest developments of his subject. Well indexed and illustrated, this volume represents with much success an increasingly important new outlook on disease, and at the same time it forms a serviceable textbook on the subject.

Pediatrics is dealt with in the well-known English "Aids" series by a volume of over 300 pages of small print with the awkward title of *Aids to the Diagnosis and Treatment of Diseases of Children*.<sup>3</sup> Dr. F. M. B. ALLEN has revised the late Dr. John McCaw's work for a sixth edition, and an amazing amount of information is contained in a very small space. The section on artificial feeding has been modified, and is certainly simple, but much too brief. References to recent work on rickets have been incorporated, and a different classification of nephritis is now adopted, while other parts of the book have been brought up to date, so that the popularity of this introduction to pediatrics is likely to be maintained.

## DIATHERMY.

THE second edition of Dr. E. P. CUMNERNATCH's book on *Diathermy, its Production and Uses in Medicine and Surgery*,<sup>4</sup> has been overdue for some time, the first edition having been published as long ago as 1921. Knowledge of this method of treatment has grown, and its scope has widened accordingly in the interval, and this means that the greater part of the second edition has undergone extensive review, and a considerable amount of new matter has been added. The result is that the volume has increased in size by more than a hundred pages, and the number of illustrations has been doubled.

The chief additions are those referring to the uses of diathermy in many of the diseases peculiar to women, and in diseases due to the gonococcus. The surgical part has been entirely rewritten and now includes a fresh section on the new "cutting currents." The author lays stress upon the important point that treatment by this method of the cause of an arthritis, such as by applications to the diseased cervix uteri, yields results which are far better than those brought about by treatment of the joints alone.

In our review of this book in 1921 we called attention to its value, especially as it was almost wholly based upon the author's own experiences. We would again emphasize this point. Dr. Cumberbatch's book is the standard work on the subject in the English language.

## FERMENTS

FERMENTATION.

THE book on ferments and their action by C. OPPENHEIMER has long been known as one of the standard works on ferments. The first two volumes of the fifth edition of this work have recently been completed, and the third volume, which deals with methods of ferment investigation (*Die Methodik der Fermente*; OPPENHEIMER and PINCUSSEN<sup>2</sup>), is now appearing in parts. The editors explain that in previous editions the descriptions of methods were mingled with the general text, but this method was unsatisfactory, and in the present edition all descriptions of methods have been collected into one volume, which completes the general work and also forms a practical textbook which can be used independently of the previous volumes. The aim of the editors has been to provide in a single book all the information needed in the laboratory by those investigating ferment action.

We have received the first two parts of this volume, which will be completed in five parts. Each contains about 300 pages. It is indeed a striking tribute to the rapidity of growth of the science of biochemistry that a work of this size should be devoted to the description of the technique of one branch of the science. The first part is devoted chiefly to general matters, and contains articles on important physical methods such as polarimetry, refractometry, nephelometry, spectral photometry, and colorimetry. These are followed by articles on physico-chemical methods—namely, the determination of viscosity, of surface tension, of hydrogen ions, of electrical conductivity, and of osmotic pressure. Another article describes Pregl's technique for micro-analysis. Next the preparation of biochemical products is discussed, and two articles by Levene on the nucleo-proteins and phosphatides are specially noteworthy. The larger portion of the second part is devoted to the description of methods for isolating ferments from vegetable and animal tissues. An article by K. Herter on the isolation of important organs in animals is of particular interest; it contains thirty-four illustrations and consists practically of a treatise on the comparative physiology of the digestive organs. In another article Bickel gives a full description of the operative procedure for making fistulae of various kinds.

Judging from the parts which we have received it would appear that the completed volume will fulfil its purpose admirably. It will provide an exhaustive laboratory manual of the greatest value to all workers who are specially interested in ferments, and it will cover also a large proportion of general biochemical technique. The publishers are offering each volume for M.28 to those who subscribe before completion of the work, which is expected by April; after that the price will be increased.

PHYSIOLOGICAL STANDARDIZATION OF DRUGS.

*Methods of Biological Assay*,<sup>6</sup> by Dr. J. H. BURR, is a book which caters for an urgent need, for it will be indispensable to all who are interested in the physiological standardization of drugs. Dr. H. H. DALE summarizes thus the merits of the work in the closing words of an introduction that he has written:

"Dr. Burn's book comes at a time when the need for it is certain to be felt. In this year the application of certain biological standards has become in this country for the first time a legal obligation, and there will be many needing guidance in the methods of their use. Here they will find no undiscriminating record. Dr. Burn has made no attempt to prepare an historical catalogue of superseded methods and conflicting evidence. He has aimed rather at a description, in practical detail, of the methods which he knows and trusts himself, I believe that many will find in him a safe and helpful guide."

Dr. Burn has an exceptionally full first-hand knowledge of his subject; he gives an exact detailed description of the

SATURDAY, MARCH 17TH, 1928.

## ACUTE OSTEOMYELITIS.

THE pathology and treatment of acute haematogenous osteomyelitis was discussed last week at a well-attended meeting of the Orthopaedic Section of the Royal Society of Medicine. The opener, Mr. Harry Platt of Manchester, reminded his hearers of the change which has come over the practice of surgery during the last generation, since the days when the master surgeons took a keen interest in the treatment of diseases of bone, which the work of Brodie had done so much to illuminate. For the problem of acute osteomyelitis is no new one, but the lure of the abdomen has led the surgeons of to-day to neglect it, so that its treatment is in too many cases left to the resident surgical staffs of hospitals. Its importance has no doubt also been diminished by the fact that the disease has become much less common, so that it seems likely to be included before long in the list of disappearing maladies. Mr. Platt quoted the Registrar-General's report for 1926, which shows that in England and Wales in that year no more than 417 deaths were attributed to this cause, whereas there were in the same period 2,710 deaths from acute appendicitis. Moreover, the average number of deaths from acute osteomyelitis during the six years 1921-26 was only 435. In the great general hospitals of London few surgeons have the opportunity of treating more than two or three cases a year, although an exception must be made in the case of the London Hospital, where, as Mr. Alan Perry told the Section, thirty-five cases were treated in one children's ward in 1925, all under the surgical control of one surgeon. At Ancoats Hospital, Manchester, all the cases admitted come into Mr. Platt's care, and the forty-one cases there treated in the last five years formed the subject of his paper, together with the large experience of Dr. Clarence Starr of Toronto, who has treated 207 cases in twelve years—an average of over seventeen yearly.

According to Mr. Platt, Starr's work, which was first introduced to the surgical public by an article in the *Archives of Surgery* in 1922, must change some of our views of the morbid anatomy, and consequently of the treatment, of the disease. It is generally admitted that in a long bone the most common seat of the primary infective embolus is in the metaphysis—that region of cancellous bone which lies between the medullary cavity and the epiphyseal line—and it is commonly held that from this situation infection and pus formation spread, not only outwards to the subperiosteal space, but deeply into the medullary cavity, and thence rapidly affect the whole shaft of the bone. This last statement Mr. Platt rejects, holding that the facts brought forward by Starr emphatically contradict the direct spread into the medulla through the cancellous bone. More often the medulla is secondarily infected from the subperiosteal space through the Haversian canals. If Starr is right the "gutter" operation, which is based on the old pathology, should be abandoned. It may be necessary to explain that this term is used to mean a proceeding by which the medullary cavity is laid open

throughout its length by the removal of the anterior two-thirds of the circumference of the shaft of the bone. The object of this, as of all other operations in the earlier stages of the disease, is the establishment of free drainage and relief of tension thereby. The less common cases in which infection is conveyed to the shaft in the first place by the nutrient artery, as happens more often in the bones of the upper extremity, are in a different category, and obviously require different treatment. Treatment by early extensive removal of bone is attended by the difficulty of deciding how much bone is devascularized beyond hope, for not all devascularized bone is finally extruded in the form of a sequestrum. Portions which may seem dead may be in the end revitalized somewhat after the manner in which a bone-graft becomes part of its bony surroundings.

In the most frequent case of metaphyseal invasion Mr. Platt advocates searching for the infective focus by drilling into the metaphysis and removing a small piece of bone by means of a trephine as soon as the focus is found, so as to allow of free drainage. These measures have given gratifying results when not postponed too long. The essence of successful treatment is early diagnosis and immediate exploration and drainage. Mr. Alexander Mitchell of Aberdeen advocates the removal of a piece of cortical bone for drainage, but when the disease has extensively invaded the shaft of a long bone he has had good results from subperiosteal resection of the diaphysis. He has no fear of failure of regeneration as long as the limb is not unduly constricted and the muscles are allowed some play. These conditions he secures by the use of Thomas's splints and gentle extension. The twenty-nine cases in the Hospital for Sick Children which formed the basis of Mr. Eric Lloyd's contribution to the discussion led him to recommend a kind of compromise between the gutter operation and periosteal incision; obviously the first involves the second. Mr. W. H. Ogilvie's statistics were based on fifty-one cases treated in Guy's Hospital in the five years 1922-26. Like other observers, he found the disease to be diminishing in frequency. He condemned diaphysectomy. Mr. Alan Perry, speaking from his experience at the London Hospital, regarded the usual acute cases as pyaemic from the beginning, and this fact was, in his view, of more importance than the localized foci in the bone.

Acute osteomyelitis is a dangerous and crippling disease chiefly affecting children. Those who suffer from it, if they survive, too often do so only after long suffering and prolonged suppuration, with its attendant risks. It is most often caused by transmission through the circulation of the *Staphylococcus aureus* from a superficial lesion, such as a sore on the skin, to the focus in the bone; and, bearing in mind this fact, some surgeons maintain that in all cases, by the time that bone symptoms are detected, we have to deal, not with a local bone disease, but with an acute general toxæmia. This may be true, but local treatment is none the less sound, more especially seeing that most of the speakers in this discussion declared themselves pessimistic about the value of blood transfusion, or intravenous medication, or other methods of attempted attack on the general condition. It is generally agreed that early drainage is most desirable; but early drainage depends upon early diagnosis, and this again depends on recognition of the prodromal stage, which, although in a fulminating case it may only be of two or three days' duration, yet in most severe cases lasts at least seven days, and may, be prolonged to four weeks.

The teaching of Sir James Mackenzie on the importance of recognizing the beginnings of disease, and of the role of the general practitioner in their detection, is generally accepted. In the case of acute osteomyelitis we must look to the general practitioner to be on the alert to notice the occurrence of fixed pain and tenderness at the end of a long bone, especially when accompanied by intermittent limping and culminating in swelling at the site of pain and tenderness. It is common knowledge that in the past the early stage of acute osteomyelitis was too often mistaken for acute rheumatism; but acute monarticular rheumatism in a child is not very common, and, remembering the paramount importance of early diagnosis and treatment in this disease, it would be well if osteomyelitis were given the benefit of the doubt, and if every practitioner confronted with the above-mentioned signs and symptoms had osteomyelitis in his mind instead of acute rheumatism. The postponement of surgical intervention in a case of arthritis is of little moment, whereas it may be of the gravest import if the case prove to be one of osteomyelitis. In this connexion it would be advantageous to ascertain the relative frequency of monarticular acute rheumatic arthritis in children between the ages of 7 and 15 years.

### "THE REALITY OF DELUSIONS."

THE realm of mental pathology affords few problems at once so obscure and so fascinating as those which concern the origin and manifestation of hallucinations and delusions. The relationship of these two phenomena is close, as every medical practitioner who has had to fill up a lunacy certificate is only too well aware. An hallucination is a percept without sensory foundation in the environment. It is not a true percept, because something is perceived where nothing is; but it partakes of the qualities of a percept inasmuch as the victim of an hallucination has an immediate belief in its outward reality. A delusion is less easily defined, if, indeed, it be at all definable. A delusion has been described as a false conception and persistent belief, impregnable to reason, of what has no existence in fact; but such a definition is inadequate from the point of view of psychiatry, for the delusions of the insane are based upon realities of a kind, realities whose nature it should be the duty of the psychiatrist to discover. It is to this task that Dr. Henry Devine addressed himself in the Long Fox Memorial Lecture delivered recently before the University of Bristol, and its title, "The reality of delusions," indicates the paradox.

Dr. Devine has chosen a topic upon which his wide psychiatric experience entitles him to speak with authority, and all the more because that experience has been deeply tinged with rare philosophical insight and enriched with wide scientific knowledge. In a singularly lucid exposition of an intricate subject he accepts a wider formulation for the interpretation of these psychotic manifestations than any purely psychogenetic or biogenetic hypothesis. Many years' clinical experience of all types of mental disorder has led him to the view that, in their ultimate analysis, the psychoses are no more than obscure forms of organic disease. Such a view is not necessarily antagonistic to a psychological theory of causation. The two—as it seems to him, and to us—are complementary rather than contradictory. They envisage different aspects of the same reality. "The total reality," says Dr. Devine, "is not revealed by exclusive reference

to either the unconscious biological or the conscious psychological process. The total reality is a biopsychic process. We are dealing with the organism as a unity, one and indivisible." He quotes in support of this view the case of a patient who believed that he had the gift of flight. The delusion bore no relation to pre-existing beliefs, to personal interests, or to problems upon which the patient might have pondered. "He will not so much as lift his head to observe an aeroplane. It is evident that no connexion exists in his mind between *that* flying and *his* flying. The delusion is inspired from within, and not suggested from without; and it clearly belongs to an altogether different category of belief than one derived from the social milieu. . . . it is the outward and visible sign of an inward reality—the symbolic expression of endogenous or organic disturbances. It is invested with the same 'reality-feeling' as perceptions stimulated from without, because it is itself an intuitive perception of organic stimulations from within."

In illustration of his thesis Dr. Devine draws a contrast between the attitude of a patient towards physical and mental illness respectively. "Both types of malady are the expression of disturbances of the organism; but in the one case the patient realizes he is ill, and can more or less localize and describe his sufferings; while in the other, in most instances, the patient has no sense of illness, and he is unable to furnish any information as to the nature or locality of the stimuli responsible for the morbid psychic products which surge into his conscious life. Thus the morbid state of the organism is not represented in the mind of the patient as physical suffering, but as depression, unappeasable anxiety, a feeling of guilt, delusions of omnipotence or persecution, or in the form of visual, auditory, or conaesthetic hallucinations." We cannot be reminded too often that psychiatry is part and parcel of general medicine, although it has a terminology (and, indeed, in some hands, a jargon) of its own. Dr. Devine is well aware that the living organism "is not quite the same thing to the psychiatrist as it is to the general physician," and that psychological medicine, groping too often at present in the dark, has to find its way by means that are not always too intelligible to the busy family doctor. But his philosophical outlook, and the freshness and clarity of his writing, lead one to hope that the gap between this special branch of practice and medicine at large is narrowing rather than widening. Every step towards integration, whether taken by way of contrast or of comparison, is a move in the right direction.

Dr. Devine compares the evolution of a delusion to the unfolding of an instinct. At first a sense of anxiety, discomfort, and tension—the consciousness of changes in the organic life for which the patient is unable to account; then the crystallizing-out of the delusion, and a new sense of power and purpose. "Just as hunger"—to quote once more from this stimulating essay—"is the echo of normal physiological distress, so a delusion is the echo of morbid physiological distress—the symbol of diffuse and unlocalizable changes occurring in the depths of organic life. Hunger does not originate in the brain, but in the depleted cells of the whole organism. It is thus also with a delusion; it is the conscious symbol of a morbid state of functioning of the whole organism." The delusion is real, for it is the symbol of organic actuality. Once again, then, mental disorder is not a thing apart; its investigation and alleviation are intimately bound up with the science and practice of medicine as a whole.

## ASTHMA RESEARCH.

SYSTEMATIC investigation of a morbid process, when well planned, wisely directed, and adequately financed, offers the best hope of advance in treatment. We are glad, therefore, to publish the appeal by the Asthma Research Council at page 468 for the sum of £50,000 to enable this distressing condition to be the subject of co-ordinated research. Breadth of vision has not always been manifest in the study of problems of disease and its treatment, the main clinical objectives being sometimes forgotten in the study of interesting scientific details; from such a danger the present proposal is obviously safeguarded. It may be recalled that towards the end of last year a group of persons suffering from asthma was formed to organize such a research, and we pointed out at the time that such an undertaking required the collection and collation of information already available, team work, and the establishment of out-patient departments where specialists of different kinds could co-operate. One illustration of the importance of such specialist study was immediately forthcoming, for Sir James Dundas-Grant, in our next issue, emphasized the significance of the rhinological element in asthma, and Mr. W. S. Syme later insisted that antral disease could not be overlooked in this connexion. The formation of an advisory medical committee to the council was welcomed in our columns on November 26th, 1927 (p. 997); it was at once apparent that the extent of the field to be cultivated had been fully realized in a practical way by the early appointment of a physician, a laryngologist, a physiologist, a radiologist, a dermatologist, a psychologist, and a biochemist, with the subsequent co-operation of a bacteriologist. Surgeon Rear-Admiral Jeaus, who undertook to act as honorary secretary of this medical committee, has since been engaged in laying the foundation of the whole scheme, and the time has now come when it is possible to appeal widely for financial support of a well conceived and skilfully devised plan of research. It is obvious that very much will depend on the response of the lay public, and we therefore commend to medical practitioners the suggestion at the end of the committee's letter that the work of the Asthma Research Council should be brought to the notice of their patients, particularly those afflicted with asthma.

## THE PHARMACEUTICAL SOCIETY'S LABORATORIES.

The second report of the pharmacological laboratories opened by the Pharmaceutical Society about two years ago deals with the events of 1927. In the course of the year the new vitamin department came into operation, and it has been experiencing an increased demand for its services, while since the beginning of August, when the Therapeutic Substances Act came into force and the laboratory began to take its predestined place in the administration of that measure, much larger numbers of samples of pituitary extract have been received for examination. The main body of the work has consisted, as before, in the prosecution of pharmacological research, with special regard to the investigation of methods of assay, and the examination of manufacturers' products by biological tests. The number of samples received for testing during the year, excluding those received by the vitamin department, was 126, the most numerous being pituitary extract, digitalis, tincture of squill, and liquid extract of ergot, others including strophanthus, cannabis indica, and the oestrus-producing hormone. In testing digitalis the recommendation of the Geneva Conference—that only those samples should be considered satisfactory which did not differ in potency from the international standard by more than 25 per cent.—is no longer followed; owing to the fact that a considerable number of samples submitted

exceeded the upper limit of strength recommended, a form of certificate specifying the degree of strength has been adopted to cover tinctures of this character. The vitamin department has completed examinations on behalf of manufacturers of three samples of cod-liver oil for vitamins A and D, and of a number of other preparations for vitamins A, B, C, and D. The results of a series of research operations carried out at the laboratories have already been made generally available through one medium or another, among them being one dealing with the standard adopted for the biological assay of squill, mentioned in a review of the first annual report of the laboratories on May 14th, 1927 (p. 889). A mixture in equal parts of nine tinctures of squill has been taken as standard, and tinctures tested are considered satisfactory which do not differ in potency from this standard by more than 25 per cent. In connexion with clinical investigations into the action of drugs on the uterus—work done in conjunction with Mr. Aleck Bourne of Queen Charlotte's Hospital—an interesting point is raised. Examination of the active principles in ergot has shown that, while the specific alkaloid (ergotamine or ergotoxine) and histamine exert a considerable effect, tyramine is inert. The action of histamine, though powerful, is relatively evanescent, and the evidence, the report states, makes it clear that the traditional value of ergot for promoting prolonged uterine contractions post partum is due to the specific alkaloid alone. It is stated that the amount of histamine in the liquid extract of ergot of the *British Pharmacopoeia* is much too small to have even a temporary effect in the dose employed, and contains none of the specific alkaloid; so that the extract of ergot prepared according to that formula since then can have had no medicinal value. The report argues that since this position arose through the Pharmacopoeial Committee rejecting scientific evidence and basing its action on the general approval of many medical bodies, the demonstration given of the uselessness of the watery extract should be taken to show that in many cases the clinician cannot form any opinion of the value of his remedies, and that the only trustworthy evidence he can offer is represented by a slow formation of opinion which takes many decades to complete.

## HEATING OF LARGE HOUSES.

A REPORT has been issued dealing with an investigation into the merits of that system of warming large buildings known as the "panel system." This name refers to the fact that steel pipes, through which hot water is made to flow, are concealed in the walls or ceilings of rooms behind panels. These panels are surfaces of plaster three-quarters of an inch thick, painted over in cream colour. The internal diameter of the pipes is half an inch. Through the pipes which are in groups of parallel tubes, the hot water at 135° to 140° F. is pumped, the temperature of the return water being about 120° F. This system of heating is essentially one in which radiant heat is supplied at a low temperature—low as compared with, for instance, a gas fire where the temperature may be as high as 2,000° F. The actual temperature of a panel may be 99° F. when the temperature of the air nine inches from the edge of the panel is 64° F. Putting on one side coal fires and gas fires as sources of heat quite unsuitable for heating large buildings, Dr. Vernon and his co-workers have studied all of the following methods: (1) The panel system of hot water tubes concealed in the walls and (or) in the ceiling; (2) under-floor heating by hot-water pipes, after the design of G. H. Widdows of the Derbyshire County Council; (3) a system of heating by means of electric current sent

<sup>1</sup> A Physiological Investigation of the Radiant Heating in Various Buildings. By H. M. Vernon, M.D., and M. D. Vernon, M.A., assisted by Isabel Lorrain-Smith, M.A. Industrial Fatigue Research Board. Medical Research Council Report No. 46. London: H.M. Stationery Office. 1923. 2s. net.

through tubes (1½ inches internal diameter), some of which were above the floor of a room and near to benches which ran across the room, while the others were placed under a skylight that occupied two-thirds of the roof area; (4) warm air from stoves, which was circulated under the floor, as in the new Cathedral at Liverpool. This last method of heating the floor by hot air is practically the old Roman method of heating by the hypocaust, remains of which may be seen in a number of ruined villas belonging to the time of the Roman occupation of Britain. As installed at Liverpool Cathedral, Dr. Vernon found that with air delivered into the ducts at 150° F., and with a floor temperature of about 70° F., the air temperature could be maintained at from 60° to 74° F., according to the spot where the observation was taken. Apparently, for very large stone floors, this system has much to recommend it. In Widdows's system, with a floor temperature of between 71° and 80° F., the air could be maintained at about 57° F. Turning now to the panel system, it is evident that Dr. Vernon finds much that is good in that method of heating. He studied panels placed in the walls of large offices, and also in the ceilings of offices, workshops, hospitals, and schools. By ceiling heating alone the temperature of the air of a schoolroom could be kept at 60° F. in cold weather, when the temperature of the water was 135° F. and that of the ceiling panel 100° F. In the summary we are told that "in offices and other buildings heated by concealed panels in the ceilings or walls there is a remarkable uniformity in the distribution of the heat, and the air temperature may be steady to within 1° F. all over the room and at all levels, except that a few inches below the ceiling (in a ceiling-panel room) there may be a rise of about 2°." "The radiation from gas fires and coal fires differs from that from panels, since it may be a thousand times more intense. . . . With such high temperature radiation rooms felt comfortably warm when 7° cooler than convection-heated rooms. In panel-heated rooms, however, the permissible reduction of air temperature was less than 2° . . . Under-floor heating, though it produces a very even distribution of heat, is apt to be unpleasant to the feet"; and finally, "Hot-water radiators of the ordinary type cause an uneven distribution of heat and a considerable temperature gradient; but they are valuable for checking the down draughts from large windows, which arise even in panel-heated rooms." The report is illustrated by twenty-six figures, ten tables, and four photographs. These last include one of the thermopile and the standard surfaces used in its calibration, the uncovered pipes of a wall panel, and those of a ceiling panel in the course of construction.

#### THE LEAGUE OF NATIONS AND THE OPIUM TRAFFIC.

At the recent meeting of the Council of the League of Nations at Geneva, attention was directed to the numerous international conventions which, though numerously signed had nevertheless not been ratified or put into operation. A crucial case was that of the International Opium Convention signed at Geneva in February, 1925, but still inoperative because three out of the necessary seven ratifications by members of the Council of the League are still lacking. When the unsatisfactory position of this inoperative convention, signed two years ago but still unratified, was reported to the House of Commons on February 15th, it is not surprising that the question was asked whether the recalcitrant signatories had any intention to ratify. Meanwhile the Hague Opium Convention of 1912 remains in operation. It will be recalled that the Geneva Convention of 1925, while formulating elaborate machinery for supervising the international commerce in manufactured narcotic drugs, did not include the American principles of limitation of production of opium and coca and the suppression of opium smoking. These principles,

which the American delegates urged as being implicit in the Hague Convention, were not adopted by the prolonged conferences held at Geneva in the autumn of 1924, and their omission led to the withdrawal of the American delegation, followed by that of the Chinese. At recent meetings of the Council and of the Advisory Committee on the traffic in opium, the Italian delegate has taken an independent line in regard to the relationship which should exist between the proposed Board of Control for the traffic in drugs and the secretariat of the League of Nations; he appeared to hold that with the Hague Convention, and the machinery, now available, of the Council, Assembly, and Advisory Committee of the League, all that was desired and all that was contemplated by the Geneva Convention might be accomplished. As regards India, it is to be noted that the acreage under poppy cultivation is in course of reduction, but the export trade of Indian opium is still very large; in 1926 this amounted to 1,224,140 lb. Much of this is consigned to the Far East, and is used for smoking, but 88,000 lb. was sent to this country as "medical opium." The net revenue of the Government of India from opium amounted in 1925-26, according to a recent statement by Lord Winterton in the Commons, to Rs.2,03,52,437.

#### A STUDY OF RHEUMATISM IN CHILDREN.

In the February issue of the *Archives of Disease in Childhood* Dr. A. P. Thomson describes a study of the distribution of rheumatic infection in some 800 Birmingham children. A rheumatic bureau has been established at the children's hospital of that city, and cases notified by the school medical service and from the children's hospital are included in his statistics. From a consideration of the influence of density of population on rheumatism Dr. Thomson's conclusion is that, broadly speaking, the more dense the population the greater the incidence of the disease. Nevertheless, there is a high incidence in many districts which are sparsely populated. There seems no clear association between poverty, scarlet fever, measles, or diphtheria and the incidence of rheumatism. A map of Birmingham and its suburbs in relation to water supply is given, and on the whole this appears to be the most significant factor elicited by Dr. Thomson's study. Dr. Robert Marshall of Belfast in the same issue, reviews 180 children suffering from rheumatism, chorea, and carditis. He arranges them into five groups, according to the symptoms and the severity of the lesions. The condition of the heart was studied by means of the electro-cardiogram, and in 33 of the 72 cases examined there was a normal record. Of the 119 children observed only two had sinus arrhythmia, and the author thinks this bears out Sir James Mackenzie's dictum that sinus arrhythmia is a sign of a healthy heart muscle. As treatment he gives salicylates for many months. He pleads for further work on the prevention of rheumatic heart disease, and for the supervision and care of the rheumatic child.

#### SEGMENTAL RESECTION OF THE COLON.

At a meeting of the Surgical Section of the Royal Society of Medicine, held on March 7th under the chairmanship of Mr. Warren Low, Dr. de Martel of Paris read an interesting paper in which he described the general principles governing the treatment of cancer of the large bowel. He emphasized the difficulties occasioned by the infected condition of the intestinal wall above the obstructive lesion, and put forward a strong plea for the performance of a preliminary caecostomy prior to the carrying out of any operation of a radical character. In the course of his remarks, which were illustrated by admirable coloured

diagrams, Dr. de Martel paid a high tribute to the operative methods he had had the opportunity of witnessing in London, and in particular referred to the value of Mummery's suggestion for the oblique division of the bowel when effecting an end-to-end anastomosis. During the subsequent discussion it became clear that French practice and British practice in relation to segmental resection for cancer and other conditions of the colon are almost identical. Mr. Mummery made the encouraging statement that cases of cancer of the colon appear to be coming to the surgeon for treatment at an earlier stage of the disease than heretofore, and in the course of his remarks he referred to the value of a transverse incision in dealing with growths at the splenic angle. Mr. Rowntree also referred to the help he had derived from this type of incision, and in connexion with the question of diagnosis he entered a plea for the more routine use of the barium enema, which he had found to be of infinitely greater use than the more tedious process of tracing a bismuth meal in its course through the large bowel. Sir Charles Gordon-Watson referred to the interest and value of these international discussions, and expressed his complete agreement with the general principles outlined by Dr. de Martel.

#### TYPOGRAPHICAL USAGE.

It is not yet three years since the twenty-seventh edition of *Rules for Compositors and Readers at the Oxford University Press* was reviewed in our columns, and already another edition has been called for.<sup>1</sup> It is quite obvious, therefore, that this little work appeals to a much larger circle than that implied in the title, which, by the way, might be altered in future editions, for it is only necessary to glance at its contents page to realize how useful it must be to all who are engaged in work of a literary character. In our notice of the last edition we gave an account of how the book came to be offered to the general public; those curious to know are referred to the *JOURNAL* of June 6th, 1925 (p. 1041). The present edition contains a few—very few—additions, otherwise it seems to be identical with its immediate predecessor. It is not necessary to repeat all that has been said in praise of the work or otherwise, but we would like to return to the subject of hyphenated and non-hyphenated words. Mr. H. W. Fowler, in his *Dictionary of Modern English Usage*, says: "The chaos prevailing among writers or printers or both regarding the use of hyphens is discreditable to English education." This, alas! is but too true, and it is a moot point whether the lists of hyphenated and non-hyphenated words published in the *Rules* are likely to assist in bringing order out of the chaos to which Mr. Fowler refers. In our last notice we gave a few instances in which the use or non-use of the hyphen seemed anomalous; it would be easy to make considerable additions to those instances. In the list of medical terms (p. 30) "foodstuffs" is printed as one word; in the general list of hyphenated words it appears with a hyphen. Quite a number of terms which are generally printed as one word are given a hyphen; on the other hand, some of the hyphenated words now commonly appear as two words. Two very accomplished journalists, who might well have claimed to be termed stylists, had a dislike for the too frequent use of the hyphen, and on more than one occasion requested that where possible it should be omitted. After all, its use or non-use is perhaps largely a matter of taste or temperament, and if the lists in the *Rules* were compiled for the first edition, which was published in 1893, it is easy to imagine that present-day taste may differ from that of the compiler. The pity (in this respect only) is that the *Rules*, which were intended especially for compositors and

proof readers at the Clarendon Press, should have been adopted by the editors of the *Oxford English Dictionary*, which is likely to be the standard work of reference for generations—and deservedly so. We still think the word printed as "sensorimeter" (p. 32) should be "sensormeter," and we are quite sure that "manio-depressive" (p. 27) should be "manic-depressive." The list of medical terms may be of use to general printers, who perhaps come across one only now and again; it is, however, not nearly comprehensive enough for those engaged entirely in the production of medical work. Some sections of the book should prove most useful. We have space to refer to one only, and that a short one entitled "Abbreviations used in the metric system of weights and measures" at page 83. This section is chosen because, in dealing with the "copy" sent in by various contributors, it is a comparatively rare event to meet with the abbreviations given here. The following may be quoted as instances: e.c. or cc. is frequently written for cubic centimetre instead of c.cm.; egm. for centigram, instead of eg.; mgm. or mgr. for milligram, instead of mg.; we sometimes get c.m., and it is only by the context that it is possible to say whether centimetre or cubic millimetre is intended. Then, too, the letter s is added for the plural form, and sometimes insisted on by the author. Various abbreviations for gram are given by different writers; we have seen "gr." (generally used for grain), "g," which is rather common, and "gm," which is adopted by the *Rules*. It is perhaps best that both "gram" and "grain" should be spelled out; it is so easy to mistake one for the other, particularly if the dot over the i in "grain" is omitted. We remember an instance where "gram" had been set up by the compositor for "grain," and the error was only detected in the final proof. The word was used in connexion with the dosage of a highly poisonous drug, and the consequences might have been disastrous had the mistake gone through. Enough has been said to show the importance of this section; in it we notice that "dekametre," "dekagram," and "dekalitre" are printed as here, with a k instead of the more usual c; this seems rather pedantic, and Fowler, in his *Modern English Usage*, favours the c. In conclusion we should like to say that we have found the book of great service; it has been our companion for years, and comparatively few days pass in which it is not consulted in this office—generally with success. Our experience must be that of others, or the editions would not continue to be issued at such frequent intervals—this is the twenty-eighth, and the fourteenth for publication.

#### OXFORD OPHTHALMOLOGICAL CONGRESS.

THE eighteenth annual meeting of the Oxford Ophthalmological Congress will be held on July 5th, 6th, and 7th, under the presidency of Mr. Philip H. Adams. The members will assemble at Keble College (where accommodation has again been offered) on the evening of Wednesday, July 4th, and on the following morning a symposium will take place on "The ultra-violet ray," introduced by Professor Leonard Hill and Mr. W. S. Duke-Elder. The Doxey Memorial Lecture will be delivered on the morning of July 6th by Professor Arthur Thomson, his subject being "Observations on the eyes of birds." One afternoon will be devoted to demonstrations in the Scientific and Commercial Museums. The annual dinner of the Congress will be held on July 5th in the Hall of Keble College. The full programme will be issued in June. Mr. Bernard Gridland (Salisbury House, Wolverhampton) is again acting as honorary secretary.

THE KING has appointed Sir Hugh M. Rigby, K.C.V.O., to be Serjeant-Surgeon to His Majesty in succession to Sir R. Havlock Charles, Bt., G.C.V.O., K.C.S.I., who has been appointed Honorary Serjeant-Surgeon.

<sup>1</sup> *Rules for Compositors and Readers at the University Press, Oxford*. By Horace Hart, M.A. The English spellings revised by Sir James A. H. Murray, M.A., LL.D., D.Litt., and Henry Bradley, M.A., Ph.D. Twenty-eighth edition (the fourteenth for publication). London: Humphrey Milford, 1928. (54 x 34, pp. 135. 2s. net.)

# Dawson Williams Memorial Fund.

## FIRST LIST OF SUBSCRIBERS.

SIR DAWSON WILLIAMS retired from the Editorship of the *British Medical Journal* on January 19th last after thirty years in that position and nearly fifty years' close connexion with the Editorial Department. In a valedictory leading article on January 21st we anticipated that his resignation would be followed by some public recognition of the long and splendid services he had rendered to the British Medical Association and the profession, to medical science, and medical literature. A provisional Executive Committee was formed almost immediately, and on February 25th we announced the steps that were being taken to promote a testimonial which should give the profession as a whole an opportunity of acknowledging our late Editor's devoted work for the science and practice of medicine. Two days later Sir Dawson Williams died suddenly, and the plans for a testimonial during his lifetime had, alas! to become plans for a memorial.

Sir StClair Thomson, who is acting as Treasurer, told our readers last week of the many messages that had already reached him from far and wide in support of the project. We feel confident that the Fund will now go forward and produce a worthy monument to a great benefactor of British medicine. Its precise form will be for the Executive Committee to decide upon in consultation with the subscribers, but they will no doubt be guided by the knowledge that Sir Dawson Williams, shortly before his death, expressed a wish that the money raised should be used as an endowment for the furtherance of medical research by way of scholarship or prize; in this way his name would be linked with work that was always very near his heart.

We print below the first list of supporters—those whose names were received up to March 10th. Further contributions will be welcomed, and will be acknowledged in these columns in due course. Though the Executive Committee does not wish to limit the amount of individual donations, it hopes that the sum eventually received will include a large number of contributions of two guineas or less, and so represent the profession generally. Cheques should be made payable to Sir StClair Thomson, and sent to 64, Wimpole Street, London, W.1, and the envelopes marked "Dawson Williams Memorial." The amount so far received is £733.

## THE PROTECTION OF MATERNITY.

YET another conference on the role of the midwife in relation to maternal health was held, under the auspices of the Midwives' Institute, on March 7th, with Sir FRANCIS CHAMPNEYS, Bt., in the chair. After some brief opening remarks by the MARCHIONESS OF SALISBURY and Lady BERTHA DAWKINS on the place of the practising midwife in rural and in town areas respectively, a discussion was started by Dr. J. S. FAIRBAIRN on the general question of the midwife in relation to normal labour.

Dr. Fairbairn said that the ideal was to have the midwife in charge of normal labour, with the doctor available for emergencies. If a doctor was retained by a patient for her confinement it was for the outstanding reason that something more than normal labour was expected—the patient wished for anaesthesia and for as speedy a termination of her trials as nature would allow. It followed that there was more intervention in labour than there should be. Some doctors had stated that forceps were used in half the deliveries they attended, whereas in institutions the forceps cases did not represent more than perhaps 3 per cent. With all intervention there was a slight rise in morbidity, which accounted for an appreciable addition to the mortality when multiplied by so many cases. He quoted figures from the Lying-in Hospital which showed that there had been 1,200 deliveries in the district served by that institution without a single death, and more than 1,000 deliveries in the hospital itself—these being, of course, the more difficult cases—with only four deaths. These figures suggested that a service conducted by well-trained and experienced midwives would give the best results possible.

Dr. J. A. WILLET, speaking of the place of the midwife in connexion with the consultant, said that the first function of the ante-natal centre was to manage normal pregnancy and

to treat such minor illnesses as might occur; its second function was to decide on the prognosis of labour. Either the ante-natal centre should be staffed by people who had had actual experience in maternity hospitals, or else the consultant should be more widely used. In the urban district the main difficulty was sepsis, and this was largely due to intervention during labour under unsuitable conditions. In rural districts the problem was rather that of accidents, and for this it was difficult to suggest a remedy, though it was to be hoped that by really good ante-natal work cases likely to give rise to any difficulty might be selected beforehand.

Dr. W. H. F. OXLEY, who spoke, from thirty years' experience of East End practice, on the place of the midwife in relation to the general practitioner, said that thirty years ago the position of the midwife was nothing like what it was to-day. The medical practitioner formerly was dependent almost entirely for the nursing of his case upon women wholly untrained. Since then not only had the Midwives Act altered the position, but the National Health Insurance Act had made a great difference. Following upon this latter, doctors had to a large extent given up midwifery, and now, in the working-class districts of London, the majority of women were attended by the trained midwife, who was the right person to attend normal labour. Conditions being what they were, normal confinements were better treated by midwives. The doctor had not the time to give to the case. Remembering that he had perhaps fifty patients waiting for him at his surgery, the doctor was tempted to hasten delivery by means of forceps. The fault was not his; it was the system under which the doctor formerly had to work. The well-trained midwife called in the doctor when anything became abnormal; it was the badly trained midwife who failed to do so. He added that the East End Lying-in Hospital was the first in London to start definite ante-natal work. Last year only required instrumental delivery, attended, of which seven only required instrumental delivery, and there was only one case of pyrexia due to a septic condition, though there were a few others which had temperatures due to prevailing influenza. He thought that the rule that a midwife should not call in the doctor unless the temperature reached

100.4° F. was too rigid. He added that the life of a practising midwife was not a happy one. Some means of obtaining a better livelihood for the midwife in a working-class district should be sought. Here was a direction in which the approved societies might help by a subsidy. Maternity benefit, it was true, was already available, but this was primarily for the provision of necessities and comforts for the mother. He thought it undesirable that when the midwife had called in the doctor the doctor's fee should be recovered from poor persons by the local authority which had paid it in the first instance, because this action made the position of the midwife an unpleasant one, and the reflection that it would be taken might deter her from calling the doctor in. The economic position of the midwife deserved much consideration. It was told of the Hebrew midwives Shiprah and Punh, who did not obey the edict of Pharaoh, that "God made them houses." The reminder was a suggestive one for public authorities or approved societies.

Sir FRANCIS CHAMBERNEYS said that a temperature of 100.4° F. was by no means the only thing for which, according to the rules of the Central Midwives Board, the doctor might be summoned. The words of the rule were of the widest possible description—"in case of any abnormality."

Mrs. BRUCE RICHMOND spoke of the inspection of midwives. No inspector now, she thought, was a person who had received no midwifery training, but comparatively few inspectors had themselves been district midwives, and sometimes the emphasis was laid on the penal rather than on the educational aspects of inspection. Finally, dealing with the economic position of the midwife, Miss LAXTON said that 110 to 130 cases a year represented the maximum that a midwife could be expected competently to handle, and she thought the wholly inadequate sum of £150 a year would be found to be about her average remuneration.

### LIVER EXTRACT FOR THE TREATMENT OF PERNICIOUS ANAEMIA.

The following further statement has been received from the Medical Research Council for publication:

Following the appearance last week (*BRITISH MEDICAL JOURNAL*, March 10th, p. 398) of the preliminary report by the Medical Research Council upon the use of liver extract in the treatment of pernicious anaemia, numerous requests have been received by the Council for particulars of the method of preparing the extract. It is accordingly thought desirable to publish the details of the process by which the material was prepared for the trial organized by the Council.

It is to be noted that the method described below is based upon the American process, of which an account had been published by Cohn and his co-workers. As was stated in the Council's report, this particular modification has not necessarily any peculiar value as compared either with the original process or with possible alternatives, but the experiments made for the Council have shown that it is one which is capable of ready application on a large scale, and which, according to the clinical indications, yields a satisfactory product.

The method is as follows:

To 100 kg. minced fresh ox liver add 132 litres of 80 per cent. alcohol and 109 c.cm. of 50 per cent. (vol.)  $H_2SO_4$ . Stir frequently and filter after twelve to eighteen hours. Suspend the tissue again in 250 litres of 50 per cent. alcohol, stir frequently, and filter after twelve to eighteen hours. Evaporate the combined filtrates *in vacuo* to a volume of about 10 litres. Add 10 litres of absolute alcohol. A flocculent precipitate is formed, which settles. The supernatant fluid is removed and the residue is centrifuged and washed with 50 per cent. alcohol. The alcoholic liquid and washings are combined, evaporated *in vacuo* to as small a volume as possible, and then poured, with constant stirring, into ten volumes of absolute alcohol. The syrupy liquid is slowly dehydrated by the alcohol and assumes a toffee-like consistency. This material is pulled into long shreds to expose fresh surfaces to the dehydrating action of the alcohol. When the dehydrating action of the alcohol is exhausted it is replaced by fresh alcohol, and the material is broken up and eventually becomes brittle. It is then filtered off and dried (*in vacuo* over  $H_2SO_4$  or by other suitable means). It is then powdered rapidly and again dried as before. The material must be exposed to the air during these operations as little as possible, as it is very hygroscopic. The dry powder is transferred to tubes, each of which should contain an amount equivalent to 250 grams of the original fresh liver.

## Scotland.

### Progress in Public Health in Scotland.

Sir W. LESLIE MACKENZIE of the Scottish Board of Health, replying to a toast at the annual luncheon of the Glasgow-Aberdeen University Association in Glasgow on March 3rd, described the changes that had taken place in public health in Scotland during the last forty years, saying that in this period two or three great developments stood out. The first had been the study of the Poor Law, a social service which was still a trouble to every Government that came into power. Much of the change in society which was going on before their eyes owed a great deal to the quiet, clear, and philanthropic working of the Scottish Poor Law. Another important matter had been that of tuberculosis. In 1906 there was no special institution for the care of the tuberculous, although this disease was at that time responsible for nearly 10,000 deaths each year in Scotland. To-day there were 5,000 beds in hospitals and sanatoriums available for tuberculosis cases, and they therefore now stood well in regard to provision for treating this disease. In 1903 investigations were undertaken on behalf of the Royal Commission on Physical Training. At that date no school board in Scotland had any medical officer, while to-day there were no fewer than 130, and, what was more important, in the 3,000 schools receiving State aid and teaching about 840,000 children, some 240,000 of the latter were being examined, prescribed for, and treated. The subject of infant mortality was one of the study of which had developed rapidly during the war. In 1915 a statute was passed allowing any local authority in Scotland to provide for the care of the health of expectant mothers, nursing mothers, and children up to the age of 5 years. As a result over 90 per cent. of the population was now in varying degrees provided with full maternity and child welfare services. National Health Insurance was another important matter which had come in during the period under review, and with some twenty statutes bearing upon the subject there were at present approximately 1,750,000 insured persons in Scotland. Whatever criticism was directed at this matter it must be admitted that medical services of an admirable sort had been provided for the Scottish people by the 1,600 doctors who were involved. The greatest enterprise, however, in the opinion of the speaker, was that of the Royal Commission on Housing in Scotland. Something like 400 expert witnesses were examined and all parts of Scotland were visited during the four years in which the Royal Commission sat. The housing department was now one of the largest departments of the Scottish Board of Health. Last year 20,000 new houses were completed in Scotland, making a total since 1919, when the movement began, of approximately 100,000 houses built to accommodate the overcrowded population of Scotland. They could therefore say that Scotland was beginning to overtake the centuries of arrears of housing. The newest problem was that of the proper use of hospitals. In September last Sir John Gilmour had announced a policy intended to secure that all forms of hospital service should be established in a unified, co-operative system. He thought that the Scottish Board of Health, which was in future to be the Scottish Health Department, had played its part in preparing the hospitals to deal with the new preventive medicine which would add increasingly to the personal fitness of the individual.

### Aberdeen Joint Hospital Scheme.

A conference was held on March 6th between representatives of the boards of Aberdeen Royal Infirmary, the Royal Hospital for Sick Children, the Maternity Hospital, and the University Court for the purpose of appointing an advisory committee from each of the bodies interested in the Aberdeen joint hospital scheme. Lord Provost Lewis, who presided, said that the fund had now reached a sum of £300,000, so that he thought they might, with every confidence, proceed with the plans for the erection of the new buildings required. He paid a tribute to the directors of the Royal Hospital for Sick Children for abandoning the site in Ashley Road and agreeing to build on the joint

had been treated in the wards, and there had been 645 operations. It was pointed out by Dr. George Mackay that although the ordinary income had been £1,082 and the expenditure only £905, the public should not think that this infirmary was not still in need of active support. There was a great demand for suitable accommodation for sufferers from eye diseases, particularly for children, in Edinburgh, so that it would be highly desirable if this useful institution were able to extend to meet this want.

### Medical Inspection of School Children.

### Census Report for Belfast.

The eighty-eighth annual report of the Crichton Royal Institution, Dumfries, for the year 1927 has just been issued. Dr. C. C. Easterbrook, the physician superintendent, in his report, states that the number of patients on the register at the end of the year was 990, an increase of 21 over the number present on the last day of 1926. During the year there had been 299 admissions, 20 discharges, and 78 deaths. The total number of cases treated had been 1,268, including 592 male and 676 female cases. Of the total number, those who had been admitted on certificate had been 735, while the voluntary patients numbered 255. The total number of private patients under treatment during the year had been 865, of whom 230 had been admitted during the year, including 167 by voluntary admission, or 73 per cent. The rate-aided patients, who were all certificated, numbered 336 on December 31st. Attention is drawn to the increasing tendency to voluntary entrance into this mental hospital. While some of the voluntary patients could have been certified, they had had sufficient insight into their condition to recognize the need for treatment in a mental hospital and to sign the required application. With regard to the causes of insanity among the patients admitted, impairment of bodily health had appeared in nearly all cases. This stress manifested itself most often in such forms as general debility, malnutrition, anaemia, heart disease, and arteriosclerosis, bronchitis, dyspepsia, and nephritis. Organic brain disease had been a cause in 8 per cent., influenza in 5 per cent., while insanity connected with the critical epochs had manifested itself in 29 per cent. at the change of life, 25 per cent. in youth, and 11 per cent. in old age. The strain of childbirth had been a cause in 6 per cent., and mental perturbation, such as worry, anxiety, and grief, had been present in 29 per cent. Alcoholic excess was a factor in 8 per cent. of men and 3 per cent. of women, and head injury in 2 per cent. With regard to forms of mental disorder, among the 299 cases admitted melancholia had affected 21 cases, delusional insanity 20 cases, mania 18 cases, confusion and stupor 18 cases, dementia praecox 8 cases, epileptic insanity 5 cases, dipsomania 3 cases, while there were 6 cases of congenital amnesia. There had been 7 cases of organic psychoses, including 3 cases of general paralysis, 2 of insanity after apoplexy, 1 of bulbar paralysis, and 1 of encephalitis lethargica. With regard to the deaths, 78 patients had died during the year, including 49 certificated and 29 voluntary cases. The general death rate was 7.9 per cent. of the average daily number. The direct causes of death were senility, pneumonia, and pulmonary tuberculosis, each 20 per cent., heart disease 12 per cent., exhaustion 8 per cent., and general paralysis 4 per cent. The average age at death was 56 years.

The annual meeting of the Eye, Ear, and Throat Infirmary of Edinburgh was held at 6, Cambridge Street, on February 27th; Mr. William C. Johnston presided. The report showed that the number of individuals who had attended the eye department during the past year had been 3,477, while the ear, nose, and throat patients had numbered 1,524. With regard to in-patients, 322 patients

of city workers, with the improvement in transport facilities, to make their homes in contiguous country or seaside areas. From the same cause may arise the fact that the proportion of the population which is normally occupied has risen from 45.3 per cent. in 1911 to 48.9 per cent. in 1926. The average age has increased by nearly 2 years since 1911, and is now 28.5 years. The report contains much information regarding housing, employment, valuation, and statistics relating to education, religious, and birthplaces, in addition to the usual analyses of age composition and condition in relation to marriage.

#### Irish Free State Dentists Bill.

The Irish Free State Dentists Bill, being in its origin and principles on the same basis as the Medical Practitioners Act, was recently passed through the Dail, and it is believed will be passed through the Senate without material change. The bill, apart from a section which restricted unquestionably the extent and nature of the practice of medical practitioners qualified after its passage, had the full support of the nine medical men in the Dail. The Minister, Mr. McGilligan, refused to withdraw this section, but left its fate to a free vote. The medical members strongly urged its rejection, and succeeded in defeating it by a very decisive majority, although the Minister was supported not only by his Ministerial colleagues, but also by the front Opposition Bench. The bill provides a close connexion between the medical and dental professions. Three of the nine members of the Dental Board are to be nominated by the Medical Council in the Free State, and the Medical Council, when it deals with matters affecting dentists, will include three members of the Dental Board.

## England and Wales.

#### Cancer Campaign in the North-West of England.

PRINCE HENRY, as president of the Lancashire, Cheshire, and North Wales Council of the British Empire Cancer Campaign, supported by the civic and university authorities, inaugurated the movement there by addressing meetings in Liverpool and Manchester on March 6th. It was announced that funds amounting to £66,000 had been received or promised. At the Liverpool meeting Prince Henry referred to the association of the city with the study of tropical diseases, and said it was proposed to establish a number of cancer research institutes, the work of which would be carefully co-ordinated. Professor Blair Bell, director of the Liverpool Medical Research Organization, appealed for co-operation between the laity and the medical profession, and emphasized the value of publicity. He outlined the methods adopted by the Research Organization. Such an investigation was, he said, special only in being concerned with a specific growth process in the tissues, which was probably not due to any one specific cause. There were many predisposing factors which induced in a cell a common precancerous condition, and the problem turned on the history of the cell's change from a normal to an abnormal state. In their work so far they had received nothing but confirmatory evidence of their original hypothesis. Prince Henry, in his Manchester speech, recalled the work undertaken in that city in connexion with cancer, reference to which was made on February 18th (p. 282). The task of the citizens, he said, was to equip their scientific leaders with adequate means; plans were being made to unite the scientific facilities of the University and the city in a common fight. Sir William Milligan, who is chairman of the Manchester centre of the campaign, emphasized the importance of teaching the public that cancer was a local disease primarily, the only safeguard being immediate treatment. The Vice-Chancellor of the University said there was no more practically important research than the investigation of cancer. Mr. T. Stott, honorary treasurer of the Christie Cancer Hospital, stated that it had been intended to appeal for funds to build a new hospital. To avoid having two appeals it had been decided that half the sum collected

in the area and allotted to Manchester should be apportioned for the prosecuting of research, and the other half should go to the support of the hospital. Search was proceeding for a new site on which to erect a well-equipped building with at least twice the present bed accommodation.

#### British Spas Federation.

The British Spas Federation held its annual meeting at Bath on March 8th and 9th, when Councillor C. H. Hacker, chairman of the Baths Committee, Bath, presided, and representatives were present from all the British spas. A presentation was made to Mr. John Hutton on his retirement from the honorary secretaryship of the federation. The necessity for strong combined propaganda on behalf of the British resorts, especially in America and the Overseas Dominions, not only by the spas, but by all interests affected, was one of the chief points discussed. Plans were made which will, as they can be developed, bring the attractions of Britain to the notice of travellers from these countries who have hitherto had their minds filled only with the propaganda of the Continent. It was stated that under the federation's scheme for bringing spa treatment within the reach of insured persons, so far as the spas are concerned, it will be possible very shortly for any approved society to avail itself of the facilities of spas and send its members for treatment. This proposal for relieving the suffering and economic loss resulting from industrial rheumatism can be adopted without any capital expenditure. The report of the scientific subcommittee was adopted, standardizing for the British spas the method of expressing analyses of the waters; the saline constituents will in future be shown as ions and in parts per 100,000. It was also decided to adopt the millimicrocurie as the unit for the radon (radium emanation) estimate. The standardizing of the analyses and the use of modern scientific methods will assist the medical profession in estimating the suitability of the various ratios for any particular case. The federation renewed the grant to the Committee for the Study of Medical Hydrology for a further series of lectures on medical hydrology at the medical schools. A collection of lantern slides has been formed showing the various forms of treatment by baths and douches and other methods at the spas, which is available for lectures at medical societies and elsewhere.

#### Health and Cleanliness Council.

The second annual general meeting of the Health and Cleanliness Council was held at the Hotel Cecil on March 9th, under the presidency of Dr. G. F. Buchanan. This organization exists to spread information about the advantages of public and private cleanliness, and includes in its membership representatives of some 150 public bodies, mostly the public health departments of local authorities. Dr. Andrew Balfour, in a speech at a luncheon preceding the meeting, reminded his audience that there was a Scottish saying that "the cloutier (the patcher) the cosier," but the motto of the council was "the dirtier the deadlier." Nowadays it was mostly in tropical countries that this axiom came home, but it was not well to think that all was right in our own towns and villages. To the discerning eye the need for a health and cleanliness council existed in many directions; one had only to notice the conditions in the back streets of cities and the very general fouling of the pavements in all streets. Another thing which had lately come under his notice was the lack of adequate sanitary provision for the workmen engaged in the great building constructions continually rising in London. Again, food was exposed in a way which was unsatisfactory. Dirt led, if not always to danger, at least to a slackening of moral tone. Much credit was due to the public health services, but a great deal more education was needed on simple matters of cleanliness, and while the various other multiplying phases of social work were to be welcomed, the good old doctrine of cleanliness must not be allowed to retreat into the background. Dr. G. F. Buchanan said that the principles of cleanliness had already accomplished much in this country. The reason for the disappearance of typhoid fever was sanitary cleanliness, including the better disposal of refuse and the purity of

the water supply. Summer diarrhoea, again, had been practically stamped out, thanks largely to the greater cleanliness with which milk was produced and distributed. All recent public health legislation was in the same direction. The medical inspection of school children had done much to promote this object. During the year the council had distributed no less than three million copies of various publications, including posters, leaflets, and showcards. At the annual meeting which followed the luncheon methods of extending the council's work by means of cinematograph displays and lectures were discussed.

#### Maternity and Child Welfare: Revision Course in Yorkshire.

A revision course for health visitors, school nurses, and others interested in public health and social service will be held at Bingley Training College, Yorkshire, from April 19th to 26th. The course has been organized by the Public Health Committee of the West Riding County Council, and has been approved by the Ministry of Health and the Board of Education. Sir W. Arbuthnot Lane will give the opening address, and the following subjects will be included in the course. A lecture demonstration on ultra-violet rays in the treatment of rickets, anaemia, and marasmus will be given by Dr. Ethel Cassie, chief medical officer of child welfare, Birmingham, and Dr. Naughton Dunn will lecture on the prevention and treatment of common deformities. The physiology of sex will be discussed by Professor B. A. McSwiney, natal care and modern midwifery by Professor Carlton Oldfield, and cardiac problems in connexion with rheumatic infection by Dr. A. Dingwall Fordyce. Dr. R. Veitch Clark, medical officer of health, Manchester, will deal with isolation, immunization, and infection, and Dr. W. A. Potts with the psychology and mental development of children. Dr. Eric Pritchard will lecture on the diet of children under 5 years of age. Other topics will be the problem of poverty, post-natal treatment by exercises, and mothercraft. Further information, including a complete syllabus, may be obtained from Dr. J. R. Kaye, county medical officer, County Hall, Wakefield, Yorkshire, to whom applications for admission to the course should be sent before March 24th.

#### Artificial Light Treatment in London.

The London County Council a year ago approved a grant of £300 towards the cost of providing artificial light treatment in connexion with the tuberculosis dispensary schemes of the Metropolitan borough councils. The scheme was to be experimental for one year. It is now realized that the period was too short on which to have a final decision on the value of light treatment, and the experiment is to be continued for another year, the London County Council providing a further £200, which is estimated to be 25 per cent. of the expenditure to be incurred by the borough councils. The Public Health Committee reported that the general conclusion arrived at from the results so far obtained, and from information as to outside experience, was that no evidence had been given to show that any form of light was a specific treatment for tuberculous disease, but that much evidence was available to indicate that, under certain conditions and in certain cases, light treatment accelerated the cure of non-pulmonary tuberculosis; the best results were obtained when it was given as an addition to residential treatment.

#### Central Midwives Board.

The Central Midwives Board for England and Wales met on March 1st, when a letter was read from the Tyne-mouth Joint Hospital Board, stating that the conference of training schools affected by the Board's policy had been fixed for February 27th. The Board agreed to extend the approval of Dr. Williamson as lecturer to September 30th next, in order that ample time might be given for the conference to put its views before the Board. With reference to a letter from Dr. Lyster inviting a discussion of a midwife's liability under Rule E.20, the Board decided:

(a) That if a midwife had summoned medical aid in respect of some emergency, and another emergency occurred in the subsequent progress of the case, it was her duty to draw the prac-

titioner's attention to this; it was also desirable for her to transmit to him the form of sending for medical help, properly filled up and signed by her. The local supervising authority should, of course, be notified of each emergency in respect of which the doctor's advice was sought, as required by Rule E.22 (1) (a).

(b) That a note to the foregoing effect be added to the rules.

Further suggested alterations in the rules were considered, and it was agreed (1) that the alterations submitted should be approved and be forwarded to the Minister of Health for his approval; (2) that, subject to such alterations, the Minister of Health should be asked to approve the existing rules as from July 1st next for a period of five years. Observations to be made on the resolutions passed at the recent conference between members of the Board and representatives of local supervising authorities were considered, and with certain amendments were approved; it was resolved to send these to the local supervising authorities and the delegates appointed to attend the conference.

## Correspondence.

### MIDWIVES AND ANTE-NATAL WORK.

SIR,—The issue of the new ante-natal regulations and record by the Central Midwives Board raises questions of serious importance.

Ante-natal work to be effective involves a knowledge of medicine which can be acquired only by a training such as that laid down for medical practitioners. The card or case record now being supplied to midwives embraces a very comprehensive and full report on the general health and obstetric condition of the expectant mother.

While in no way wishing to limit the functions of the nursing profession, I would emphasize the danger of entrusting medical examinations of a complex nature to persons not trained in medicine. The cause of maternal mortality and morbidity is to be found, not only in obstetric complications, but in diseases such as toxæmia, or in those which affect the cardiac and respiratory organs.

One fails to see how a course of midwifery training, however good in its way, can fit a nurse to examine the heart with a stethoscope or to estimate with accuracy the relationship between the pelvis and the foetal head. Measurements at the pelvic brim do not always indicate the size of the outlet, or the difficulties that may be encountered at labour.

Doubtless regulations are issued as to calling in the aid of a medical practitioner in doubtful cases, but an observer whose knowledge and mode of examination are inadequate will still be faced with the difficulty of deciding upon the presence of abnormal conditions.

I have the utmost admiration for the splendid work being done by the midwives, and for their infinite patience during attendance at labour. I realize also that the aim of the Central Midwives Board is to obtain the greatest possible efficiency in the service. My only object is to point out that ante-natal work, one of the most difficult branches of medicine, involves considerations both in regard to diagnosis and treatment altogether different from those which apply to childbirth. At least two examinations of every maternity patient should be made by a qualified medical practitioner—one ante-natal and one post-natal. The midwife's case record would then be properly checked.

It behoves the teaching schools and other similar institutions to give facilities for intensive post-graduate courses in ante-natal diagnosis and treatment so that practitioners may have an opportunity of keeping themselves up to date in this new branch of medicine.

One aspect of the agitation regarding maternal mortality intimately touches the medical profession. There is a strong disposition on the part of some members of the public to criticize the medical practitioner's obstetric methods. For instance, your issue of March 3rd contains the report of a conference on maternal mortality which illustrates the prevalence of this spirit of adverse criticism, the main idea being crystallized in the expression "there is danger in the doctor." This is a strange tribute to a

profession which has taken the leading part in making British midwifery the admiration of the world. When all is said and done the question remains to be answered, Who trains the midwives? And was not ante-natal work originated by a medical practitioner—Dr. Ballantyne?—I am, etc.,

London, March 5th.

A. LOUISE McILROY.

#### DYSPHAGIA ASSOCIATED WITH ANAEMIA.

Sir,—In a letter in your issue of March 3rd (p. 375) Dr. Arthur F. Hurst refers to a paper on the above subject by A. Mason Jones and Robert W. Owen which appeared in the JOURNAL a fortnight earlier, and which emphasized the association of anaemia with dysphagia due to spasm at the entrance to the gullet. With regard to this affection Dr. Hurst informs us that he is "now inclined to think that any spasm which is present is secondary, the primary cause being achalasia of the pharyngo-oesophageal sphincter."

For the benefit of those readers who may be unacquainted with the term "achalasia," I should state that Dr. Hurst had it specially coined for himself to describe a state of non-relaxation. He first applied it, I believe, to the "cardiac sphincter" in cases of cardiospasm, and has since employed it in connexion with other sphincters in the alimentary tract. I am not qualified to express an opinion as to achalasia of the pelvi-rectal and anal sphincters (vide Price's *Practice of Medicine*, p. 580), but I venture to state that all my experience in oesophageal work leads me to regard with extreme scepticism the reported occurrence of achalasia at either the upper or the lower end of the gullet in man; in such cases the affection is essentially spasmodic, as has been taught for long, and is still maintained by almost all writers on oesophageal diseases.

To return to Dr. Hurst's letter. In support of the suggested change in terminology and pathology he states that the condition is "exactly analogous with achalasia of the cardiac sphincter, which was formerly erroneously described as cardiospasm." He further states that "achalasia of the cardia has now been proved, by the pathological investigations of Stokes and Rake, to be due to inflammatory and degenerative changes in Auerbach's plexus [I should mention that changes of a similar nature were found independently by Munro Cameron in Glasgow], which prevent the normal relaxation of the sphincter when it is reached by peristaltic waves carrying food down the oesophagus. If similar changes were present in Auerbach's plexus at the upper sphincter, relaxation at the beginning of the act of deglutination [sic] would be prevented."

This explanation is unfortunate, for Auerbach's plexus is not found in the highest few centimetres of the oesophagus, and consequently cannot influence the action of the sphincter at the entrance. Further, while the onset of spasm at the upper end of the gullet in some cases is gradual, in others it is sudden, and the obstruction appears to reach its maximum at once, thus excluding the possibility of an early period of achalasia. Lastly, anyone who has manoeuvred an oesophagoscope to enter the gullet of a patient suffering from the affection under consideration will have no doubt that he has been dealing with spasm.

I shall not lengthen this letter by discussing the reasons adduced by Dr. Hurst for the desire he cherishes that the term "cardiospasm" be abandoned for "achalasia of the cardia," but shall merely repeat what I have said on several occasions—namely, that in cardiospasm the closure of the lower end of the gullet is always firmer than normal, usually it is pronounced, and sometimes it is so great that it yields only to prolonged steady pressure; and that the endoscopic appearances of the affected region are distinctly those of spasm.—I am, etc.,

Glasgow, March 7th.

A. BROWN KELLY.

Sir,—Although during the last twenty years I have had referred to me a large number of cases of dysphagia due either to pharyngeal or oesophageal disease, or both, yet in only one case was I able to convince myself that I was confronted with an unequivocal instance of primary spasm. The case referred to was demonstrated at the Medical

Society of London, and showed obvious spasmodic contractions in the neck muscles as well as of the fauces and pharynx on attempted swallowing. I have, of course, seen a few instances of dysphagia high up in edentulous anaemic women in which a gross anatomic stricture was proved to be absent by endoscopic inspection, though in some other cases sent as probably functional a definite benign anatomical narrowing of the lumen of the deep pharynx and of the cervical gullet was evident endoscopically. Whether any of these latter cases are included in those recorded by Brown Kelly, Paterson, Plummer, Hurst, and others is a matter of conjecture.

Mason Jones and Owen (JOURNAL, February 18th, p. 256) accept the usual teaching that the dysphagia in the class of case under discussion is definitely due to an abnormal spasmodic contraction of a "pharyngo-oesophageal sphincter." Killian, usually so accurate a writer, wrongly described the lower of the two portions of the inferior constrictor of the pharynx as the sphincter of the mouth of the oesophagus, whereas it is obviously the sphincter of the lower end of the pharynx, and not an oesophageal muscle at all. The circular fibres of the upper end of the gullet are not aggregated so as to form a definite sphincter, and are distinct from the constrictor fibres above. This obvious nomenclatorial mistake of Killian has led to a large amount of inaccurate thinking and writing, so that the lesions and the errors of co-ordination of the lower end of the pharynx have not been accurately differentiated from those of the gullet.

Dr. Hurst (March 3rd, p. 375) now has doubts as to these presumed functional strictures at the laryngeal level being really of the purely primary spasmodic nature, thinking it more likely that there is neuro-muscular inco-ordination of the nature of want of relaxation (achalasia) of the lower portion of the inferior constrictor—that is, crico-pharyngeus muscle—which he assumes (and possibly rightly) is normally in a state of sphincteric contraction when at rest—that is, when there is no attempt at deglutition. A normal sphincteric contraction which does not give way to relaxation on attempted deglutition is, it seems to me, for all practical purposes, rather of the nature of a spasm, even though falling short of a cramp, and probably that is not far removed from the idea that Paterson and Brown Kelly and others have in mind. What I find in these cases is not active contraction, obstructive or otherwise, but a passive or feebly active condition of the musculature concerned in the pharyngeal part of the act of deglutition. In other words, the interference with the normal act of swallowing is of the nature of muscular paresis together with reduced sensibility of the mucosa rather than hyperaesthesia and increased reflex contraction. The opening up of the lumen of the pharyngo-oesophageal junction preparatory to the bolus entering the gullet is effected in normal conditions by certain lingual and hyoid muscles actively pulling the larynx upwards and forwards away from the spine. The atrophic changes in the tongue, fauces, and pharynx are slight organic changes and associated, I suggest, with a feeble reflex and a feeble muscular response during the co-ordinated pharyngeal act of deglutition. If these views are correct the dysphagia is pharyngeal, not oesophageal in location, and not entirely functional, and certainly not spasmodic, but organic. The lesions are, in my view, comparable to those found in the paretic palate of chronic nasal catarrh, where the palate is thinned, shrunken, and almost immobile, and shows atrophy of the mucosa, including the glands, and wasting of the musculature; moreover, the reflex is diminished and sluggish, and the contractile power feeble. A similar condition, I believe, obtains in many of these pharyngeal dysphagias, where swallowing is impeded owing to feeble effort and the fact that the pharyngo-oesophageal junction is not well opened up on account of impaired reflex stimulus.

I had not noted the enlarged spleen in any of the few cases I have seen of this form of dysphagia in feeble, edentulous anaemic women, for the reason that it was not looked for, unfortunately.

Although I recognize the syndrome alluded to by Mason Jones and Owen in their paper, I must add that I have met with a few cases of dysphagia in women with none

of the signs of the syndrome present, which I have had to regard as purely functional cases of inco-ordination of the deglutitory act at the lower pharyngeal level, but with no obvious hypertonic spasm, and merely suggesting an inhibition of the active opening up of the lumen of the pharyngo-oesophageal junction. Such cases correspond to some described by the older writers, who failed to distinguish between these and those which exhibit the syndrome. The latter usually show atrophic lesions in the deep pharynx, whereas the former do not.—I am, etc.,

London, W.1, March 5th.

WILLIAM HILL.

### ASTHMA RESEARCH COUNCIL.

#### *An Appeal for Financial Support.*

SIR,—The Asthma Research Council is preparing a public appeal for funds to carry out its object of increasing our knowledge of asthma and allied conditions.

On the initiative of the Council a Medical Advisory Committee has been formed whose functions are to suggest what research work at present being pursued or projected should be supported by the Council, to indicate future lines of investigations, and to supervise such work. The following preliminary suggestions have been made:

1. The formation of an asthma clinic at one or more hospitals for the investigation of the "asthma-lay-fever-urticaria syndrome."
2. An investigation into the phenomena of sensitization in relation to asthma.
3. An investigation into the nature of the asthmatic attack from the physiological standpoint.
4. An investigation into the relationship of asthma to general respiratory diseases.
5. An investigation into the family histories of asthmatic and allied conditions.
6. An investigation into the nature of alleged "cures." This would include the continuation of the work of the British and American Medical Associations in investigating secret remedies.
7. The provision of whole- or part-time research scholarships and grants-in-aid for such investigations and for others being carried out or projected by general practitioners, medical centres, or research institutions throughout the empire, which are approved by the Medical Advisory Committee.
8. The appointment, from time to time, of travelling investigators to visit foreign clinics where investigations into asthma or allied conditions are being undertaken.
9. The publication of any useful results obtained.

In order to carry out these schemes the Asthma Research Council hopes to raise a fund of £50,000, and the Medical Advisory Committee trusts that members of the medical profession will assist by bringing to the notice of their patients—especially of their asthmatic patients—the aims of the Council and its need of support. Subscriptions should be forwarded to the Westminster Bank, Ltd., Covent Garden, W.C.2.—We are, etc.,

ARTHUR F. HURST, Guy's Hospital,

*Chairman.*

R. J. S. McDOWALL, King's College,

*Vice-Chairman.*

H. W. BARBER, Guy's Hospital.

L. S. T. BURRELL, Brompton Hospital.

E. C. DODDS, Middlesex Hospital.

J. FREEMAN, St. Mary's Hospital.

R. D. GILLESPIE, Guy's Hospital.

V. E. NEGUS, King's College Hospital.

S. GILBERT SCOTT, London Hospital.

T. T. JEANS, Surgeon Rear-Admiral (ret.),  
*Honorary Secretary.*

March 12th.

### PEPTONE TREATMENT OF ASTHMA.

SIR,—I have given hundreds of injections of peptone, and ordered hundreds more, and, with one single exception, I have never had any alarming results.

Two varieties of shock may possibly follow an injection: the anaphylactic and the ordinary protein shock. In its slighter forms one often finds that at the end of a course of injections of peptone a certain large dose is reached, after which the patient becomes at once flushed, asthmatic, nauseated, and frequently sick. It is then inadvisable to give any further injections, because the same thing will

occur next time, although the whole distress is over in a few moments. This is a mild form of anaphylactic shock.

The severe case which occurred is interesting. The patient had already had a previous course of peptone given into the muscle, which had probably sensitized her. She was a sufferer from very severe asthma. I gave her the usual initial dose of three minims very slowly into the vein. In a few minutes she began to feel ill, and the respiration tightened up with increasing asthma. There was an instant demand for micturition. The asthmatical spasm developed so severely that the respiration practically stopped and the girl became insensible; the heart continued to beat slowly and strongly. By this time I had given her an injection of adrenaline into the muscle. She gradually began to come round, and at the end of perhaps three or four minutes after receiving the injection she was breathing sufficiently. She spent the night in a nursing home, and went home by herself next day. To her surprise she was free from asthma for some five weeks afterwards, presumably in an anti-anaphylactic phase, but naturally no further attempt was made to give her peptone.

Much more rarely after a small treatment dose the patient will complain a few hours later of protein shock—that is, shivering, headaches, sickness, and a high temperature.

Peptone is a recognized method of inducing protein shock when it is given in much larger doses. Perhaps a skin test is advisable before commencing a course of treatment, especially if a previous course has been given, but the possibility of an anaphylactic seizure is, I think, usually considered negligible.

The peptones I use are made up in accordance with Dr. Auld's prescriptions.

Anaphylactic deaths from horse serum are well known, and many have been quoted, especially in American literature.—I am, etc.,

London, W.1, March 8th.

FRANK COKE, F.R.C.S.

### X-RAY DIAGNOSIS OF CHRONIC APPENDICITIS.

SIR,—Recent correspondence seems to have left the question of the value of bismuth meal examination in the diagnosis of chronic inflammation of the appendix in an unsettled and uncertain position, and I offer the following observations in the hope of stimulating further investigation and discussion of the subject. These opinions have been arrived at from a considerable experience of x-ray examination with barium meals, and from operating on many of the cases afterwards, when I have been able to check the x-ray diagnosis.

In the first place one has to consider what are the pathological changes produced in the appendix by one or more logical changes produced in the appendix by one or more attacks of subacute inflammation in that structure. The microscopic changes, broadly speaking, are a round-cell infiltration and hyperplasia of connective tissue in all of the coats, but especially in the muscular coat. The result of this inflammatory change is to diminish the contractile power of the appendix, to convert it from a normally contracting part of the intestine into a more or less rigid tube.

The badly diseased appendix might almost be likened to an inert test tube opening off the base of the caecum coli, without power of contraction and depending on its being emptied of its contents by the siphon effects of the movements in the caecum. I have not found that it is possible to diagnose a chronic inflammation of the appendix from its manner of filling with barium or bismuth. The number of cases in which I have seen an appendix after operation with such a tight constriction that barium would not pass through it is very small, and so I place no reliance on filling defects in accurate diagnosis. Emptying faults, not filling defects, are to my mind the diagnostic features of an inflamed appendix as judged by x-ray examination.

The cases in which I think one is justified in giving an undoubted diagnosis of chronic appendicitis are those in which one can see the appendix filled at an earlier examination; and later examinations, which should be frequent, must show that the appendix has not emptied itself when the ileum and caecum have emptied, and the meal is in the region of the hepatic flexure, if not in the transverse

or descending colon. Further, tenderness on palpation of such a filled appendix is necessary to convict it. The rough digging in of inquisitive fingers, as referred to at the British Medical Association Meeting in Edinburgh, is of no value, but with the appendix visible under the screen very careful and gentle palpation over the inflamed organ should satisfy one that some inflammatory process has left its tell-tale tenderness behind, and that tenderness must be definitely located in the visible appendix itself.

Holding up of the opaque meal at the ileo-caecal valve is suggestive of, amongst other pathological conditions, some inflammatory trouble in the right iliac fossa, but it is not diagnostic of appendicitis. In the same way holding up of the meal in the caecum may be the result of inflammatory trouble in the appendix, but it may be due to other conditions, ranging from functional derangement to malignant growths in the bowel itself.

X-ray examination as regards the diagnosis of chronic appendicitis has its limitations, but if an appendix has been seen filled with barium, if it is tender on palpation and does not empty when the caecum has emptied, then to my mind it is proved guilty of being the seat of some pathological condition which is probably of an inflammatory nature.—I am, etc.,

York, March 5th.

J. G. CRAIG, M.B., F.R.C.S. Ed.

#### GASTRIC SECRETION OF NEUTRAL CHLORIDE.

SIR,—As Dr. Goodhart has raised this interesting question it might be worth while pointing out to your readers that there are at present two independent pieces of published evidence which show that regurgitation from the duodenum is not sufficient to account for the total chloride curve of the fractional test meal.

(1) Baird, Campbell, and Hern (*Guy's Hospital Reports*, vol. 74, p. 23, January, 1924) found that the removal of the duodenal contents by continuous suction did not cause any alteration in the free HCl or total chloride curve from the stomach.

(2) Hausman, Day, and Clifton (*Med. Journ. Austral.*, vol. 2, p. 6, July, 1927) have calculated that, supposing the stomach contents consisted of pure gastric juice of maximum concentration mixed with secretions from beyond the pylorus which also contain some chloride, the stomach would still contain less chloride than was actually found at the end of one of their test meals.

The doctrine of the gastric secretion of neutral chloride has evidently come to stay.—I am, etc.,

London, W.1, March 13th.

E. P. POULTON.

#### IMPORTANCE OF SPUTUM EXAMINATION IN PULMONARY DIAGNOSIS.

SIR,—In a note on pulmonary actinomycosis in the *JOURNAL* of March 10th (p. 404) there occurs this surprising sentence: "This patient had been regarded as tuberculous for twelve years, and during that time this diagnosis was confirmed by numerous x-ray and sputum examinations, in which tubercle bacilli, however, were never found." One would assume it to be a clerical error were it not for the fact that an alarmingly widespread distrust or contempt of the bacteriological test in the diagnosis of pulmonary tuberculosis appears to exist.

This leads to two grave errors. Firstly, the sputum is not examined for tubercle bacilli sufficiently often, and as a result a great number of cases of phthisis pass unrecognized in the early curable stage. There can be little doubt that, in the majority of cases, pulmonary tuberculosis can be diagnosed most early and most certainly by the examination of the sputum. This, with a careful survey of the symptoms, the late afternoon temperature record, and the weight record, forms by far the most important clue to the diagnosis. Yet in spite of this doctrine, which would be upheld, I think, by most experts, there are to be found those—and some even recognized teachers of medicine—who assert that it is by physical signs that the disease may be earliest detected; and the pathetic constancy of the radiologists' diagnosis of tuberculosis is well known.

The second grave error in ignoring the bacteriological test is that the observer fails to recognize those chronic

diseases that are not tuberculosis. Absence of tubercle bacilli after many repeated examinations, where there is sputum to be examined, practically excludes tuberculosis. This is not always believed, and thus we find bronchiectasis, fibrosis, syphilis, actinomycosis, spirillosis, tumour, all masquerading as tuberculosis. Moreover, when the eyes are opened and conditions other than tuberculosis are looked for, behold they are found, and we are told that they are becoming much more common than they used to be.—I am, etc.,

F. G. CHANDLER, M.D., F.R.C.P.

London, N.W.1, March 12th.

#### COLLECTIVE INVESTIGATION AND TUBERCULIN.

SIR,—I was much interested in Dr. Robert Carswell's letter in your issue of March 3rd (p. 375). I gather from his remarks that he does not consider general practitioners have the time to spend on investigating cases which might receive benefit from injections of T.R. or B.E. I presume, therefore, that his idea is to have these investigations carried out at a sanatorium or tuberculosis dispensary. If my deductions are right I should like to make a few remarks with regard to the subject.

First, has Dr. Carswell ever seen a case of pulmonary tuberculosis flare up whilst under treatment with injections of T.R.? Unfortunately it has been my lot to see two such cases, which makes one exceedingly diffident in using T.R. in cases of pulmonary tuberculosis, even if under sanatorium conditions.

Secondly, Dr. Carswell suggests trying the effect of rapidly increasing doses of T.R. or B.E. in "simple, early, uncomplicated cases of tuberculosis." I am presuming he still refers to pulmonary tuberculosis; if so, I may be unfortunate, but I see very few cases of this nature, and personally should certainly advise them to try sanatorium treatment in the first place.

Thirdly, I am quite aware that a large number of medical men consider that injections of T.R. can be given to out-patients, but as I am still dealing only with cases of pulmonary tuberculosis, I fear I must disagree with their opinions. In a sanatorium, where a strict watch can be kept on the patient's temperature, pulse, etc., and the amount of exercise taken is carefully graduated, is quite a different proposition to giving T.R. to a patient who is living at home.

In the latter case one has to trust so much to the patient himself as regards reaction—that is, rise of temperature, slight increase of symptoms, etc.—and if one also realizes that T.R. can be dangerous, I do not think that the contemplated gain is worth the undoubted risk.

Fourthly, Dr. Carswell unfortunately did not actually mention surgical tuberculosis, which in my humble opinion derives a very considerable amount of benefit from injections of T.R. In this sanatorium all cases of surgical tuberculosis have as a complication a greater or lesser degree of pulmonary tuberculosis, and very few are, therefore, suitable for injectational treatment.

Lastly, all patients suffering from pulmonary tuberculosis vary as regards their individual resistance to the disease and, therefore, a dosage which might be suitable to one case would not necessarily mean that all cases could be treated by the same increase of dose or reach the same maximum. Moreover, by means of auscultation alone a patient's resistance to disease cannot be determined, and if signs in the chest increase, then it is fairly safe to say that a good deal of damage has been done.—I am, etc.,

H. SHARPE,

Medical Superintendent, Hertford County Sanatorium, Ware.

March 8th.

SIR,—Dr. Carswell suggests the need for collective research into the treatment of tuberculosis by tuberculin so as to gain some real opinion as to their proper values. I strongly endorse this suggestion, but I should like to go further. Opinions about treatment are hopelessly at variance; some practitioners favour fresh air and sunshine, some think that artificial sunlight will cure early cases, and some believe that artificial sunlight

only acts by tending to destroy tissue, and so is not good. As regards tuberculin, most men seem afraid to use it, and from inquiries at sanatoriums I find it is rarely employed in any of them now. I am hoping his letter will help to create a fresh medical interest in the whole subject, especially the need for the following:

1. Research for a vaccine or serum or other practical means of really stamping out tuberculosis in cattle, so as to prevent bovine infection of our milk and food.
2. Overhaul of our present public health regulations so as to make it impossible for any infected food to be on sale.
3. Research into some means of earlier diagnosis in the human body than afforded by x rays or the finding of tubercle bacilli in the sputum, so as to get cases for treatment at the earliest stage.
4. Investigation of tuberculin and all the other lines of treatment which are reputed to do good in certain cases.
5. Further research so as to prepare, if possible, some kind of antitoxin for tubercle bacilli, and some official examination of the preparation of the various tuberculins, of which there are so many on the market.
6. Finally, the leading article in this week's *BRITISH MEDICAL JOURNAL* emphasizes the need for study of the question of immunity, both natural and acquired.

—I am, etc.,

London, S.E., March 3rd.

GORDON TIPPETT, M.B.Lond.

SIR,—Dr. Robert Carswell, writing in your issue of March 3rd (p. 375) to urge the need for such an investigation, quotes the question asked by the *BRITISH MEDICAL JOURNAL* so recently as July, 1927, "To what extent is tuberculin of value in the diagnosis and treatment of tuberculosis?" He quotes also the remark: "Practitioners feel that they are without guidance as to the cases in which, and the conditions under which, tuberculin is of value; guidance to which they are entitled the more, since systematic treatment by tuberculin is advocated by medical men with experience of its value." It appears to Dr. Carswell that the guidance asked for demands a thorough re-examination into the course and results of cases treated in accordance with Koch's own final conclusions and directions, and he goes on to say that, extraordinary as it may appear, adequate clinical examination of Koch's important work on this subject has not yet been accomplished to such a purpose as to carry conviction to medical opinion in general; though he notes your opinion, stated in 1911, that "already results were accumulating which should convince everyone but the incurable sceptic."

Personally I hail with delight Dr. Carswell's suggestion that the British Medical Association should undertake the direction of collective research by the various Divisions into the usefulness of Koch's tuberculin, for the reason that I should welcome any means whatever of bringing the inestimable value of tuberculins into prominence. But I would point out that we have here in London all the data and results of years and years of continuous use of Koch's tuberculins only awaiting examination and report. I refer to the classical methods now practised by Dr. W. Camac Wilkinson for the last thirty-five years. In his hands Koch's tuberculins give unparalleled results in pulmonary tuberculosis as well as in tuberculous affections of bones, glands, genito-urinary tract, skin, and even eyes. Every Tuesday and Friday afternoon (2 to 4 o'clock) he treats cases by injection of Koch's tuberculins at the Tuberculin Dispensary, 32, Fitzroy Street, W.1, where seekers after knowledge of tuberculin are welcome to see cases in all stages of diagnosis and treatment, and to examine records of cases without end, as also to see cured cases.

During the past two years, from results observed on my own cases (exceeding twenty) treated on these lines, I am left in no doubt as to the value of tuberculin when administered according to the rules laid down by Dr. Camac Wilkinson, himself a pupil of the great Koch. The words in italics are important, for I am well aware that tuberculin used otherwise has resulted in absolute failure. We come thus to the crux of all the differences of opinion on the value of tuberculin. The time must soon come when a commission will be appointed to examine and report on the usefulness of Dr. Camac Wilkinson's work; it is an

interpretation of, and the practical supplement to, Koch's own work, which has been sadly neglected for so long.

I have avoided reference to details of treatment in this letter as Dr. Camac Wilkinson himself, on July 10th, will be addressing the St. Pancras Division in the British Medical Association House on the treatment of tuberculosis in the home, when I trust that all interested in this matter will be present to hear what can be done by his method of using tuberculin.—I am, etc.,

London, W.1, March 7th.

J. GORDON HUME.

#### WET WINDS AND EARLY PHTHISIS.

SIR,—The interesting paper by Drs. Gordon and Ash in your issue of March 3rd (p. 337) merits the attention of all tuberculosis workers, though to me the figures are unconvincing.

(1) The number of cases is far too small. Expressed as percentages—worked out to two places of decimals—they appear impressive, but the individual numbers used for the calculation are mostly under ten, whereas to carry conviction they should be in the tens of thousands. Especially is this true with reference to such uncertain topics as the influence of subsoil on disease. No doubt the authors would not claim any finality, only that the figures are suggestive; but they call them "striking." It is, of course, impossible to procure a large number of patients from such a small area, but in that case some other method of testing the influence of climate on tuberculosis should be attempted.

(2) It is not clear what is meant by shelter or exposure. In Devonshire, I remember, Dr. Gordon's results, working from the map, differed in 58 per cent. of cases from the decision of other observers who actually visited the houses. And one wonders if the world generally accepts Dr. Gordon's conclusion that an elevation of 100 feet shelters an area for half a mile behind it (presumably, therefore, a mound 10 feet high would shelter an area of 88 yards). Until "exposure" is more strictly defined there is a very wide scope for difference of opinion.

(3) Devon is cited by the authors as supporting their claims, but many years' work in South Devon has led me to the contrary belief. Generally speaking, South Devon is exposed to south-westerly winds, yet tuberculous patients do as well as elsewhere, and 40 per cent. of my notifications are importations from other places, who for the most part consider that they do better here. Our tuberculosis hospital in Torquay is open only to the south-west, yet 90 per cent. of the patients admitted there improve.

The science of climatology was once described as "opinionology," and it is not yet much more exact; but medical men are expected to, and often do, give very decided opinions about the climate necessary in the treatment of various diseases. I suggest again that as a beginning the Meteorological Office might tell us the ten localities in Great Britain most exposed to west winds and the ten most protected. Independent observers could then investigate the incidence of and mortality from tuberculosis in those areas, and we should be venturing on surer ground.—I am, etc.,

Paignton, Devon, March 5th.

E. WARD.

#### THE ACUTE ABDOMEN.

SIR,—My whole intention in starting this correspondence was to rivet the attention of the profession on the appalling fact that only three out of five cases of acute intestinal obstruction survive operation. Who can be content with a 40 per cent. mortality when the cause of the trouble could often be so easily relieved if the case were submitted to operation early enough?

The danger of delay in suspected cases of all types of the acute abdomen cannot be over-emphasized. I do not advocate "look-and-see surgery" based on inexperience, but I utterly condemn, after nearly twenty-five years' experience of this class of work, a "wait-and-see" policy, which can only have one result if one is going to be sure from symptoms and not afraid from suspicions that an abdomen is "acute."

What I say has increasing value in reference to the now frequently occurring cases of abdominal injury in motor accidents. Where the history indicates that a visceral

lesion may possibly be present, beware of delay in doing an exploratory laparotomy.

I saw a case four days ago in which the only objective symptom was a small tender bruise over the left iliac fossa. The story was that the wheel of a motor had passed over the boy's abdomen. His colour was good. His abdomen was perfectly flaccid. He had no sickness. His bladder was distended and he could not pass his urine. A half-hourly observation over a few hours of an increasing pulse rate, a flicker of uneasy movement of a coil of bowel seen beneath the flaccid parietes, gave me all the indications I required that the case was one for exploration. I found the mesentery of the small intestine entirely abrupted from two inches of the ileum, and this portion of intestine, congested and paralysed, but as yet unruptured, was adherent to the back of the bladder. My suspicions were amply justified, I think, though none of the symptoms of the acute abdomen were present on which I could base a diagnosis.

Most of my friends in general practice candidly admit that they cannot make regular hourly observations in cases under suspicion of being "acute abdomens," and they are only too thankful to be able to send them to hospital "for further observation and operation if thought necessary." On my part I welcome cases at that stage from every point of view—except accommodation. This winter I could at one time have shown Mr. Billing six cases of "acute abdomens" lying side by side—all atypical pneumonias—so that I appreciate the value of his hint, and hope he knows that in such cases there may occasionally be a concurrent acute abdominal lesion.

I believe that 75 per cent. of the patients with acute abdomens who die ought to be saved, and such cases will in the future be saved by early operation when the factors controlling the situation have been properly adjusted. What a need there is for proper education and organization of the profession in regard to this type of case.

Only the last paragraph of Mr. Billing's letter has any interest. In cases of menstrual trouble, hysteria, commencing specific fevers, and poisoning I have seen associated vomiting and abdominal pain which (the physician in me, considering all the facts of the case, was able to persuade the operating surgeon in me) did not require operative treatment, but I confess I am unacquainted with that large variety of cases he writes of, where persistent vomiting associated with abdominal pain need cause no concern lest they should suddenly become "acute abdomens." I feel certain the profession will be under a debt of gratitude to Mr. Billing if he will give detailed notes of, say, six typical cases of the sort he has in mind.—I am, etc.,

Glasgow, March 4th.

WILLIAM RANKIN.

### ERGOT POISONING AMONG RYE BREAD CONSUMERS.

SM.—A good deal of interest has been aroused amongst the Jewish community by the article published under the above heading in the *BRITISH MEDICAL JOURNAL* of February 25th (p. 302).

Having been associated with a number of Jewish institutions for a considerable period, and practising as I am in a thickly populated Jewish neighbourhood, it seems strange that neither my colleagues (with whom I have consulted on the subject) nor myself have ever come across cases such as those described.

It is quite true that brown, or rye, bread is an important factor in some Jewish diets; still the figures given as to the amount of ergot it contains appear very much exaggerated, and do not approach the 22.85 grains stated to be consumed by the individual in one day.

Rye bread, according to a very reliable baker (who bakes a large quantity of this bread), only contains at the maximum 15 per cent. of rye meal. There is a coarser rye bread, called "sweet and sour," which contains about 10 per cent. more—that is, under 25 per cent. of rye flour. This is the maximum of rye meal or flour that could possibly be put into any brown bread, as bread containing a larger percentage is neither edible nor presentable. The "sweet and sour" bread is not much used, and it is principally the 15 per cent. bread that is consumed.

Assuming, as in the article referred to above, that half a pound of rye bread is consumed daily, this only represents 5 oz. of flour, of which 15

flour. Of this 15 per cent. 1 per cent. is ergotized, and it therefore follows that the amount of ergot consumed is only 3.45, and not 22.85, grains per day as calculated.

I append the following report of rye bread submitted for analysis:

"I beg to report I have examined the loaf of 'rye' bread received from you yesterday for the possible presence of ergot. I have submitted the bread to a careful chemical and microscopical analysis, and I find it is perfectly free from this poison. I have also examined the rye and wheat flours from which this bread is made, and I find they contain no trace of ergot or any other poisonous ingredient.—Dr. E. A. Wagstaff, M.Sc., F.I.C., Analytical and Consulting Chemist, Victoria University, Manchester."

This applies to the bulk of rye bread, and the examples given by your correspondents must have been taken from a very unusual batch of bread.—I am, etc.,

BERNARD HIRSON, L.R.C.P. and S.I.,  
Hon. Physician, Home for Aged and Needy Jews,  
Jewish Home for Incurables.

Manchester, March 4th.

### SHOCK AND ABORTION.

SIR.—While "anticipation," "fright," and "shame" are probably contributory causes of the sudden and often fatal shock in cases of criminal abortion, one can hardly feel satisfied that this forms a complete explanation of the condition. Especially does this seem to be likely when it is remembered that only in a very trifling percentage of instances of criminal abortion does a fatal result follow. In the case which gave rise to this discussion, and in the one mentioned by Dr. E. E. Nicholl (*BRITISH MEDICAL JOURNAL*, February 25th, p. 328), a fluid injection was used, and it seems probable that in both of these the fluid—soap and water in the one case and a disinfectant in the other—on reaching the uterine cavity, was forced through the Fallopian tubes into the peritoneal cavity, thereby causing the profound and fatal shock.

This seems to be borne out by a case which came under my notice in hospital some years ago. A woman, a gynaecological case, in the course of treatment was given an intrauterine injection; immediately after this she became profoundly shocked and collapsed. The only feasible explanation seemed to be that the fluid had reached the peritoneal cavity through the tubes, thereby causing the shock. This explanation was confirmed by her abdominal condition when the shock passed off.—I am, etc.,

T. J. HOLLINS, M.D., M.A.O.

Sandwich, Kent, March 6th.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

A MEETING of the Senate was held on February 22nd.

A resolution was adopted authorizing a variation of the trust deed establishing the Geoffrey E. Duveen lectureship in otology to allow of the establishment of a travelling post-graduate studentship in oto-rhino-laryngology, and of a fund for the promotion of research in those subjects.

The regulations for the first examination for medical degrees (Red Book, 1927-28, p. 245, second paragraph, and Blue Book, September, 1927, p. 212, fifth paragraph) were amended to read as follows:

Candidates who have been permitted to offer themselves for re-examination in any subject at the first examination for medical degrees may offer themselves . . .

Dr. J. B. Christopherson has been appointed to succeed the late Sir Percy Bassett-Smith as examiner in tropical medicine for the year 1928.

It was reported that the Registrar of the Royal College of Physicians had notified that Sir Wilnot Herringham has resigned, as from March 31st, his membership of the Senate as one of the representatives of the College, and that, in view of the reconstitution of the University, the College did not propose to fill the vacancy.

The ceremony of Presentation Day will be held in the Albert Hall on Wednesday, May 9th, at 3 p.m., and the graduation dinner will take place the same evening at 8 p.m. in the Grocers' Hall, Prince's Street, E.C.

The election of three Beit Fellowships for Scientific Research, of the value of £250, will be awarded on or about July 16th. Forms of application and all information can be obtained by letter only of application.

## ROYAL COLLEGE OF SURGEONS OF ENGLAND.

An ordinary Council meeting was held on March 8th, when the President, Sir Berkeley Moynihan, was in the chair.

*Diplomas and Licences.*

The diploma of Fellowship was granted to J. S. Fathi, who has attained the prescribed age. Licences in Dental Surgery were granted to 20 candidates. Diplomas in Tropical Medicine and Hygiene were granted jointly with the Royal College of Physicians to 44 candidates.

*Court of Examiners.*

Mr. H. S. Clogg was re-elected a member of the Court of Examiners at the expiration of his period of office.

*Central Midwives Board.*

Mr. Victor Bonney was re-elected a representative of the College on the Central Midwives Board for one year from March 31st next.

**Medical Notes in Parliament.**

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons this week considered the Air Estimates and Navy Estimates, and had second reading debates on the Local Authorities (Emergency Provisions) Bill and a bill to authorize the totalisator on race-courses. The Representation of the People (Equal Franchise) Bill was introduced by the Home Secretary. It proposes to make electoral qualifications, both parliamentary and municipal, the same for men and women, and it will enfranchise 5,250,000 additional women over 21 years of age. Of these nearly 2,000,000 will be over 30. It does not propose to alter the University franchise. The new register containing the names of the enlarged electorate will come into force on May 1st, 1929, and a general election is to be expected soon afterwards.

At its meeting on March 9th the Parliamentary Medical Committee elected Dr. Drummond Shiels its honorary secretary for the session. The Committee, of which the attendance was small, discussed the Edinburgh Corporation Bill, whose object, as previously explained in these columns, is to authorize compulsory treatment for persons suffering from venereal disease and liable to infect others, and who break off or refuse voluntary treatment. As to the wisdom of the Corporation submitting such proposals to the House of Commons members of the Parliamentary Medical Committee expressed widely divergent opinions, but they agreed on the need to emphasize the essential gravity of the disease and the need to strive for its eradication. The meeting also discussed the Dogs' Protection Bill and the Dogs Bill. The Research Defence Society was reported to be considering possible amendments, but the Committee doubted whether much could be achieved thereby.

**Invaliding from the Navy.***Suggested Re-examination of Rules.*

In the House of Commons, on March 7th, Sir BEATRICE FALLEN proposed a motion declaring it imperative that the Board of Admiralty should re-examine the rules by which the question is determined whether disability is attributable to or aggravated by service in the Royal Navy, and the manner in which these rules are attributed. He pointed out that whether a recruit entered from Greenwich School, or as a boy at 15, or as a man at 18, practically speaking, made every man and boy in the navy a "first-class life." Nine out of ten men who went up for examination were not accepted. Once in the navy the youth was well fed and well clothed, but his sleeping accommodation was, for the most part, a metal tank, with no port-holes, and only artificial light. Very often the only ventilation was that forced through by a fan. The fan caused a draught, which men did not like, and it was possible for the fan to be blocked or covered. Hammocks were slung not more than 2½ feet apart, or still closer when a ship was carrying a draft to a foreign station. These were the conditions of a world-wide service. What were the chances of a healthy man avoiding tuberculosis in them? If a man was suffering from incipient tuberculosis he dare not complain, because he knew that if he had that disease he would be discharged, and, if his service were not long, without a pension. If a man had entered since 1921 he must have fourteen years' service, in the event of invaliding, before he got a pension, unless the disease for which he was invalided was admitted by the Survey Board to be attributable to or aggravated by his service, when he got a small pension. In 1920, when there were 124,000 men in the navy, 265 were discharged for tuberculosis, and in only 3 per cent. was it allowed that their cases were attributable to or aggravated by service. Between January and September, 1926, of 151 men dismissed from the navy for tuberculosis alone, service conditions were held responsible in less than 4 per cent. The last return showed 180 cases of tuberculosis, of which 18 were certified to be attributable to or aggravated by service. Before 1914 the President of the Board of Survey was the man's own captain. That gave the rating an advantage he had not got now he was brought before a board of medical officers, however learned. Sir BEATRICE added that he did not understand the

self-sacrifice of the medical profession. There was not a naval doctor in the world who would not admit that any doctor might be wrong, particularly a civilian doctor. The sailor had the command and was sent to some part of the world which was not so pleasant, mistaken and ridiculous. There must be some kind of appeal for every rating. At present there was one to the Board of Admiralty, but that was too remote, though he instanced cases where appeals should like to see a board with a captain (R.N.) executive as a civilian of common sense and experience. The board should appoint a civilian doctor of eminence as a referee.

Rear-Admiral BEAMISH seconded the motion. He said that in 1925 2.19 per 1,000 of the men in the navy were invalided for pulmonary tuberculosis, and the death rate was 0.34. In the army in 1926, the nearest year for which he could get figures, the case rate was 0.91 per 1,000 and the death rate 0.12. Among civilians in 1926 the case rate was 1.52 per 1,000 and the death rate 0.17. Two-thirds of the men invalided from the navy for tuberculosis had over five years' service, and more than half of them were over 25 years of age. Men in the navy got tuberculosis at a higher rate than did the officers. Conditions of life in a man-of-war were very bad, so far as tuberculosis was concerned. Men often slept head to toe, with their hammocks touching, in ill-ventilated spaces. Small ships were battered down at sea in bad weather, and even in good weather ventilation was poor. He doubted whether there was anywhere such a wastage of first-class life from disease as in the navy. Until the State understood its responsibility in regard to the health of the people it employed and set up some fund, if necessary on a contributory basis, or some form of insurance, they would continue to inflict hardship on men and officers.

Mr. AMMON, in associating himself with the motion, said that not many years since tuberculosis was almost endemic in the post office, which had the highest rate for death and sickness of any calling in the country. Now it had almost been stamped out by attention to the working conditions. Investigation was needed to see whether that could be done in the navy.

Dr. VERNON DAVIES said members constantly had cases brought to their notice which appeared to deserve consideration from the Admiralty, but which were held to be non-attributable to service conditions. He had received a letter from the First Lord in 1926, in which Mr. Bridgeman said: "Where there is evidence that a man invalided for a particular disease has been exposed to exceptional conditions of the service involving the risk of contracting that disease, this evidence would be accepted as proof of attributability." Dr. Davies remarked that to prove a man had been exposed to exceptional conditions was an exceedingly hard condition to fulfil. It could be decided for accidents and certain tropical diseases. On the other hand, the Admiralty had a good case in refusing to accept as attributable to service some instances of bronchitis or rheumatism followed by heart disease. Tuberculosis was in a different category. In only two instances would the Admiralty acknowledge without hesitation that tuberculosis of the lungs was attributable to service. One was when a man had been nursing tuberculous patients; the other when he had served in a submarine in which a consumptive man had been among the crew. In every other case the Admiralty Board had proved extremely difficult to convince. To say that the case had arisen as the result of exceptional circumstances during a man's service was a matter of opinion. In 1923, 1924, and 1925 not quite 3 per cent. of cases invalided out of the navy were held attributable; that was an exceedingly small percentage. He believed that as the result of questions in that House a committee had been set up to inquire into tuberculosis. It had been sitting for some time, and he thought that as a result the Board of Admiralty was beginning to take not quite so strict a view as it did before. Two years ago he had suggested a scheme of compulsory insurance against tuberculosis. The First Lord of the Admiralty had considered it sympathetically, but the Board of Admiralty had turned it down. When these men were invalided out of the service all that remained for them was the national health insurance, amounting to about 15s. a week for a short time. Then they were sent to a sanatorium, and when they came out they were left to starve and die. If, under a compulsory insurance scheme, one penny a week were deducted from pay, every man, if Dr. Davies's scheme was actuarially sound, would have a pension of £2 a week as long as he lived.

Mr. HORE BELSHAM said that each month 5,000 men tried to get into the navy and only 500 succeeded. The principal diseases for which men were invalided out of the navy were those one would expect from the conditions of bad ventilation, bad light, noise, and confinement. They were deafness, weakened eyesight, and chest trouble. A civilian who claimed to have contracted tuberculosis out of his duty could go to a county court. A doctor who was an Admiralty servant, honest though he was, was not the proper tribunal. The place of the doctor was in the witness-box.

Viscountess ASTOR did not believe it possible to prevent a high rate of tuberculosis on a modern man-of-war. In the American navy the rate was also high.

Mr. GROVES cited cases, one of which had been reconsidered after the man's death, on the weight of medical opinion at the London Hospital. He remarked that if British ex-soldiers had a medical grievance they could go before an independent doctor.

Sir GERALD HOLLER said doctors often followed one another like sheep when they gave an opinion. An independent board was required which could decide cases in an atmosphere outside the service and on the best skilled opinion.

Mr. KELLY remarked that the Admiralty must not assume the House was satisfied with the tribunals provided in respect of the

At this point attention was drawn to the fact that forty members were not present, and that number not assembling the Speaker adjourned the House without any member of the Government replying on the debate.

### The Army Estimates.

#### Medical Services of the Army.

On March 8th Sir LAMING WORTHINGTON-EVANS gave the House of Commons his annual survey of the Army Estimates. He said he asked for a vote of £41,050,000 and for 153,500 men, 13,000 fewer than last year. Economies had been made in the R.A.M.C. Mr. LAWSON, following for the Labour party, pointed out that last year, of 84,000 recruits who offered themselves, about 28,000 were accepted as meeting the army standard of physical fitness. This was 33 in every 100, against 35 per cent. in the previous year. Sir WILFRED SUGDEN raised the question of the recognition and employment of pharmacists in the army. He said that the Army Council and the Secretary for War had never accepted the principles which had been accepted by a conference which discussed this matter in 1920. The War Office was buying its drugs and ingredients ready compounded. If these could be prepared under the control of skilled pharmacists in military hospitals there would, on market prices, be a saving of 50 to 70 per cent. in the cost. Sir RICHARD LUCE said the establishment of the R.A.M.C. was being reduced by 22 officers and 284 men out of an establishment of 4,163—a reduction of 6.8 per cent. The reduction in the rest of the army was only 0.7 per cent. He had no objection to the reduction or co-ordination of hospitals, to which this reduction of strength was officially attributed, but the hospitals must not be the criterion of the strength of the R.A.M.C. Why should they have men of the R.A.M.C. doing duty in military hospitals at all? To train the male personnel for duty in war the establishment of the R.A.M.C. must not be allowed to be based on the actual beds required in hospitals in peace time. The proportion of men in the R.A.M.C. as compared with other branches of the service was based on the experience of many years. In the late war there had been practically no breakdown of the R.A.M.C., although there was a partial breakdown in Mesopotamia, where the work fell on the Ladian Medical Service, which had been started in peace time. Since the war there had been a constant whittling down of the R.A.M.C., a considerably greater proportionate reduction than in the rest of the army. It was not a fact that medical service could be improvised in war time out of civilian medical men. For instance, it was impossible to improvise a military sanitation service in war. Sir Richard noted that Vote 10 of the Army Estimates contained £69,000 for new buildings at military hospitals throughout the Empire, but said it was impossible to tell from the Estimates how much of the £1,314,000 allocated for upkeep of military buildings was to be devoted to hospitals. Last year he had visited Netley, and found an atmosphere of gloom, a lack of paint and care, and the grounds allowed to go to rack and ruin. He appealed to the Secretary for War to look into this matter of the upkeep of hospitals. Let him visit them and compare them with a great voluntary hospital. Sir Richard Luce passed to the failure to keep up the establishment of medical officers in the service. It was difficult to say why the service did not attract fully qualified men at present. He could not say the pay of the R.A.M.C. was insufficient, but enough candidates were not coming forward. He thought a chief cause was the feeling that the service was one which was being reduced. The medical officers and their heads in the army had no direct representative on the Army Council. This constant reduction of strength caused unrest among those already serving, and made them unwilling to get other men to join. If another war came the chances were that the scapegoat would not be the Minister for War of that time or any other Minister, but the heads of the medical departments who would have to bear the blame of the piecemeal reduction which was being done now. Dr. FREEMANTLE supported Sir Richard Luce's remarks on the medical services. Medical members of Parliament felt that they were entitled to urge an extension of these services in some directions, as they had pointed out the futility of keeping up general hospitals for both the army and the navy in the same place in peace. The medical members of Parliament urged the Government to see whether they could economize further in that direction. The medical services consisted of two parts. The tactical part, consisting of physicians and surgeons, could to some extent, especially in connexion with the Territorial Army, be improvised in time of war, but the administrative part, the nucleus of every unit, could not be inserted unless it had been trained. Yet in the Territorial Army, for instance, despite representations from medical members of Parliament, the number of field ambulances in a Territorial division had been cut down from three to one. In the East Anglian Territorial Division that field ambulance unit had subsequently been cut down from three sections to two, and it would be necessary to form three field ambulances in case of mobilization to serve three brigades. There would be great difficulty in expansion, and he maintained that the reduction was excessive. The personnel of the Territorial Army medical services was down by one-third of its full strength. In the Regular Army they had still the difficulty of recruiting. They had managed at last to get fifteen medical officers compared with the sixty required. They could not support an army in the field unless they had an adequate supply of medical officers trained for the work. The Secretary of State had the matter fully in hand, and perceived the difficulty in getting these men recruited. The real difficulty was not simply the question of pay, but the fact that the men now in the service were overworked abroad, and, instead of getting leave, were constantly kept abroad beyond their time, the senior men being relied on to do comparatively junior work, because there were no junior officers in the service. They were

practically deprived of a great deal of their family life when they were getting towards the end of their service. These men did not give a good name to the service at home, and that made it all the more difficult to get the junior men. He hoped the Secretary for War would get the advantages of the service home to the junior men he wished to attract. Mr. MITCHELL BANKS spoke of the value of good dentistry in maintaining the health of the soldier. In cantonments in India, even in peace time, if teeth went wrong there was nothing to do but to have them out, and in no skilful manner. Dr. VERNON DAVIES associated himself with Sir Wilfred Sugden's remarks concerning pharmacists in the army. The navy thought it necessary to have trained pharmacists who had gone through a professional training and examination. So did the Ministry of Health under the national health insurance scheme, and the Home Office for the prisons. If the War Office was right they should scrap the pharmacists in the navy, prison service, and national health insurance organization, and get the work done by cheap dispensers. He commented on the failure of the Secretary for War to speak about the medical service when introducing the Estimates. Yet an army without doctors was of no use. There was something wrong with the service. Instead of having competitive examinations they now had to go to the medical schools to persuade men to go into the army. Had the Secretary of State inquired what the trouble was? Had he done anything to see if the service could be made more attractive to medical men? The present salary was extremely good. There was too much moving about from place to place, and when officers retired after seven years or so the gratuity was not high enough. The War Office must remember that it was competing with panel practice and with all the public medical appointments in this country. When a young medical man, soon after he had qualified, could go into public medical service and work five days a week for £700 or £750 a year as a doctor, he had no definite inducement to go into the army. A short service in the army with either an increased gratuity at the end of the seven years, or, preferably, with retired pay, giving the War Office a call upon the doctor at any time, would increase the popularity of the service. If it could be arranged that any medical man who had served in the army should have preferential treatment in any State or municipal appointments of medical men, that would further make the service popular.

Replying to the debate, Sir LAMING WORTHINGTON-EVANS said the War Office had been able to accept some of the recommendations made by a committee of pharmacists. To accept others would have involved a good deal of extra expense. The R.A.M.C. dispensers received adequate training for their duties, enabling them to dispense the prescriptions of the medical officers. The adoption of the policy that the hospitals of the three services should be at the disposal of patients of any one of them entirely accounted for the reduction in R.A.M.C. personnel. Some of the personnel which appeared to have been reduced had gone to China, and were carried on a Supplementary Estimate. Nevertheless, the reduction was inevitable. Sir Richard Luce had complained of the atmosphere of military hospitals. Sir Laming said he had visited most of them. Absence of paint was not the test of a hospital. The test was the medical service and the social service which patients in these hospitals received. His experience was that real human attention was given to the men in the hospitals, who seemed to be happy and content with the treatment they received. Sir Richard Luce had suggested that the medical service was treated as a Cinderella service, that cuts were made upon it out of proportion to the cuts made on the rest of the army. That was not so. In these Estimates, out of a total of £41,000,000, £2,400,000 was devoted to the medical service. They had not the number of doctors required for establishment. They had done their best to make the service attractive. He had conferred with his medical advisers and with the medical societies, and thought now, at any rate, the terms and conditions of service were agreeable to the medical profession. He had the endorsement of the medical profession. Men could now join for seven years, and if they then wished to retire they had a gratuity of £1,000—a very useful addition to the capital of a young medical man about to set up in practice. A pension of £1 a day had been given to majors retiring from the R.A.M.C. Sir Richard Luce had complained that R.A.M.C. officers were not directly represented on the Army Council. Every branch of the army could not be represented on the Council, but the Director-General of Medical Services had direct access to the Secretary of State.

A motion to reduce the strength of the army by 50,000 men was defeated, and the Estimates passed through Committee.

### Pensions.

Answering Mr. Scrymgeour, on March 8th, Major TRYON said that at Dundee for more than a year past the medical facilities at the disposal of pensioners had not involved attendance by a medical officer otherwise than on a part-time basis. The medical service was working well and no complaints had reached him. In case of emergency the services of an examining medical officer residing in Dundee were available.

In a reply to Mr. Robinson, on March 7th, Sir KINGSLEY WOOD said a man disabled in the great war who was insured under the National Health Insurance Act was entitled to the ordinary course of his insurance to medical benefit, including treatment for his war disability, so far as it did not involve special skill and experience which general practitioners as a class could not be expected to possess. An uninsured man was entitled to similar treatment if in receipt of a disability pension and not in receipt of a total income over £160 a year.

On March 13th Sir L. WORTHINGTON-EVANS told Mr. Barnes that the fact that an ex-service man was in receipt of a disability award was not in itself a disqualification for appointment to a

temporary commission in the Royal Army Medical Corps. Such cases, however, had naturally to be considered very carefully in view both of the possibility of aggravating the disability and of the danger of the officer's breakdown in the performance of his duties.

In reply to Dr. Shields, on March 13th, Lieut.-Colonel G. F. STANLEY stated that the total number of disabled officers, nurses, and men in receipt of pension or other grant from the Ministry of Pensions in Scotland was approximately 43,000. In 1925 the average number of patients attending at Ministry clinics in Scotland, and in receipt of in-patient treatment, was 960 in the clinics and 600 in the Ministry hospitals; in 1926 the average was 610 in the clinics and 495 in the hospitals; and in 1927 425 in the clinics and 365 in the hospitals. The number of disabled men who, in 1927, received treatment at home together with allowances was 1,484. The Ministry had in view hospital accommodation in Scotland for current needs of about 400 beds, which would provide a substantial reserve. In view of the decline in the requirements of hospital treatment he was unable to estimate what accommodation might ultimately be found to be necessary. There were 105 Scottish disabled men under treatment in Ministry hospitals in England. Of these 99 were in four hospitals—namely, Harrowby, Orpington, Cosham, and Maghull—which had been established for the treatment of special forms and degrees of nervous disease, including epilepsy. Six were medical and surgical cases, receiving special treatment in Mossley Hill (1), Sidcup (2), and Rochampton (3) hospitals.

#### *Dr. Voronoff's Experiments on the Improvement of Livestock.*

On March 13th Mr. GUINNESS told Mr. Bromley that Dr. Serge Voronoff had not been invited to visit this country in connexion with the improvement of livestock, but a scientific mission was recently sent to Algiers by the Ministry of Agriculture and the Scottish Board of Agriculture to inquire into the results of Dr. Voronoff's experiments. The report of the mission had just been published. Arrangements were being made for carefully controlled experiments to test the claims made on behalf of Dr. Voronoff's work. These experiments would not be carried out by the Ministry, but by university workers, whose work was aided by Government grants. All experiments on living animals calculated to give pain were subject to licence and inspection by the Home Office, under the Cruelty to Animals Act, 1876.

*Small-pox.*—Mr. CHAMBERLAIN told Lord Henry Cavendish-Bentinck, on March 8th, that he had evidence of small-pox having been spread during the recent epidemic by persons admitted to the casual wards of Poor Law institutions. He had given instructions that, for detection of small-pox, all persons admitted to casual wards should be medically examined.

*Preservatives for Cream.*—Sir J. GILMOUR, on March 13th, in reply to Mr. N. Maclean, stated that he had been unable to assist milk-sellers in Scotland to find an alternative preservative for cream in place of those prohibited by the Order, which was now coming into force. Sir KINGSLEY WOOD also informed Mr. Lamb that the Minister of Health's attention had been drawn to the increasing use of emulsifiers for the reconstitution of cream, but it did not seem likely that the Preservatives Regulations were responsible for the increase. The prohibition of preservatives applied equally to natural and to reconstituted cream. A more probable explanation could be found in the fact that the latter article was said to be prepared at a cost much lower than that of the former. He was unable to state how many prosecutions had been instituted by the local authorities in respect of the sale of the synthetic article as cream. The constituents of cream could be emulsified so as to produce an article very similar to natural cream. Investigations were, however, being made as to the possibility of distinguishing between the two articles by scientific methods. Pending the completion of these investigations, he was not in a position to indicate what further steps could be taken by the Ministry of Health.

*R.A.F. Hospitals.*—In a statement furnished to Dr. Vernon Davies on March 9th, Sir SAMUEL HOARE shows that the Royal Air Force maintains six hospitals—Haltom, with 309 beds and 9 hospital officers; Cranwell, with 100 beds and 6 officers; and Uxbridge, with 10 officers, and Basra, with 35 beds and 5 officers, in Iraq; and 31 beds and 4 officers—all at home; Hinaidi, with 200 beds and Sarafand, with 77 beds and 5 officers, in Palestine. These establishments were under review. He added that the hospitals in Iraq and Palestine provide for British army officers and certain British civil officials in addition to the R.A.F. The personnel attached to most of the hospitals performed duties apart from those directly connected with the hospitals. For instance, the officers at Cranwell Hospital were also medical officers for the Cranwell Command.

*Inspection of Factories.*—The HOME SECRETARY announced, on March 8th, that he proposed to proceed in the autumn with the appointment on a committee to report on the strength of the factory inspectorate. This will probably be a departmental committee. In announcing this decision the Home Secretary remarked that he had admitted the number of factory inspectors was inadequate.

*Experiments on Animals.*—Sir W. JOYNSON-HICKS, replying, on March 12th, to Mr. N. Maclean, who asked if he had caused any inquiry to be made as to the large increase in the number of experiments performed on living animals, and, if so, whether any reason had been given for such an increase, said that the increase was mainly in inoculations, feeding experiments, and

similar procedures. He understood that it was due principally to the development of medical science in regard to the standardizing of drugs and the investigation of vitamins, and to the steps taken to safeguard the purity of the milk supply. He saw no ground for special inquiry.

*Anthrax.*—In a reply to Dr. Vernon Davies, on March 8th, the HOME SECRETARY said that in the years 1925 to 1927 the cases of anthrax reported as occurring in factories and other premises under the Factory and Workshop Acts numbered 125, of which 17 were fatal. Wool and hair other than horsehair caused 60 cases with 8 deaths (18 and 1 in 1927), horsehair or bristles caused 14 cases with 4 deaths (3 and 1 in 1927), hides and skins caused 46 cases with 5 deaths (13 and 1 in 1927); feathers, bones, felt, tanned leather, and refuse were responsible for 5 cases (1 in 1927) with no deaths.

#### *Notes in Brief.*

An interdepartmental committee has been examining the law relating to poisons, and the Home Secretary will bring to its notice the remarks of the coroner at a Kensington inquest in favour of action to restrict the import of the French hypnotic drug known as dial.

In the West of Scotland 157 factories employing young girls were not visited by factory inspectors last year, but 86 had been visited within fifteen months, and all but 6 within two years.

In only three unions in England and Wales are no beds, bunks, or hammocks provided for casuals. In these unions improvements are under consideration.

Special arrangements have been made by the Metropolitan Hospitals Board, with the approval of the Ministry of Health, for provision of treatment for young persons suffering from the after-effects of encephalitis lethargica with a view to research into appropriate methods of treatment.

The Ministry of Health has been in communication with the French Ministry of Agriculture concerning an alleged discovery of a remedy for foot-and-mouth disease.

Colonel HEARNLAW, on March 7th, stated that no naval hospitals at home or abroad had been closed during the past three years on account of co-operation with other service hospitals.

## The Services.

### DEATHS IN THE SERVICES.

SIR ROBERT NEIL CAMPBELL.

Colonel Sir Robert Neil Campbell, K.C.M.G., C.B., C.I.E., Bengal Medical Service (retired), died at Lahore, when on a visit to India, on February 18th, at the age of 73. He was born on September 28th, 1854, the son of Robert Campbell, of the British Linen Company's Bank, Trinity, Edinburgh, and educated at the Edinburgh Institution and at Edinburgh University, where he graduated as M.B. and C.M. in 1876. Entering the I.M.S. as surgeon on October 1st, 1877, he attained the rank of colonel on April 2nd, 1909, and retired on April 2nd, 1914. After a few years' military service, during which he served in the Naga Hills campaign of 1879-80 on the North-East Frontier, was mentioned in dispatches on C.G.O. No. 123 of 1880, and received the Frontier medal with a clasp, he entered civil employ in Assam, where he was for several years civil surgeon of Shillong, the capital of the province. In 1900 he was transferred to Bengal, and till his promotion to the administrative grade filled the post of civil surgeon of Dakka, one of the most important medical appointments in Bengal. On promotion he became inspector-general of civil hospitals in the short-lived province of Eastern Bengal and Assam, created by Lord Curzon in 1905. After the Royal Durbar of 1911 the arrangements made by Lord Curzon were cancelled, Eastern Bengal was reunited to Western Bengal, while Bihar and Orissa were cut off from Bengal to form a new separate province, and Assam again became a small province by itself. When these changes were made Campbell became I.G.C.H. of Assam. After his retirement in April, 1914, he had barely settled down at Lochmaben, in Dumfriesshire, when the great war began, and he rejoined for service. He was then appointed to the command of the Pavilion and York Place Hospitals at Brighton for Indian soldiers. For his services in that capacity he received the K.C.M.G. on June 4th, 1917. He previously held the gold medal of the Kaisar-i-Hind Order, first class, from May 23rd, 1900, when that decoration was first given; the C.I.E. from June 25th, 1909; and the C.B. from June 4th, 1912. In 1881 he married Ethel Bensley, and had two sons and two daughters. His elder son, who was in business, took a commission in the King's Own Scottish Borderers at the beginning of the war, was severely wounded in Flanders early in 1915, and died of wounds in hospital in England soon after; his younger son, who was in the Indian Army, was killed in Gallipoli in the summer of 1915.

## Obituary.

### JAMES WHEATLEY, M.D.LOND.,

President of the Society of Medical Officers of Health.

We announced, with much regret, in our last issue, the death of Dr. James Wheatley, president of the Society of Medical Officers of Health, and for twenty-seven years medical officer of health for the county of Shropshire.

James Wheatley was a student of King's College, London, and obtained the diplomas of M.R.C.S.Eng. and L.S.A. in 1886, graduating M.B., B.S.Lond. in the year following, and proceeding to the degree of M.D. in 1890. He obtained the D.P.H.Ed. in 1891. After holding the post of house-physician at King's College Hospital he was for some years medical officer of health for Blackburn, and in 1901 he succeeded Dr. Charles Porter, who was appointed medical officer of health at Johannesburg, in the county appointment in Shropshire. In this position he distinguished himself by his honest enthusiasm for progress in public health matters. His schemes for the improvement of the people's health were always notable for their careful thoughtfulness and soundness of judgement. His report on tuberculosis culminated in the opening of the King Edward Memorial Sanatorium at Shiretton in 1912, while the co-ordinating of the work for crippled children resulted in an organization probably more complete than in any county in the country. He was a practical believer in the benefit to be derived from propaganda work, and in this he did not spare either his time or his energy.

Wheatley was slow in coming to conclusions, carefully balancing the pros and cons of every question, and often reserving judgement. But having formed his opinion on the course of action to be advised, he was a consistent advocate, and had no reluctance to be in a minority. He held confirmed views on the relation of diet to the incidence of dental caries, and these he earnestly advanced when occasion arose.

Dr. Wheatley was a member of the British Medical Association, and served on the Public Health Committee in 1922-23. In 1925 he was elected a member of the Council of the Shropshire and Mid-Wales Branch, was president of the Branch from May, 1925, to October, 1926, and vice-president in 1927.

A colleague writes: Wheatley's extremely thoughtful and original habit of mind was never better exemplified than in the presidential address which he delivered in October last, on his installation to the chair of the Society of Medical Officers of Health. That society mourns not only the loss of its president, but also the loss of one of its most conscientious, reliable, and lovable members. As late as last summer Wheatley was questioning his own wisdom in allowing himself to be elected president. He was not in the best of health, and in November he had to forgo the privilege of presiding at the society's annual dinner. Instead, on advice, he took a long rest in a nursing home, and characteristically he urged that his illness should only be spoken of as a temporary indisposition. He had previously had occasional heart attacks, and apparently these became more severe. About a month

ago Wheatley had an influenzal illness from which he was recovering, when, on the evening of March 3rd, having been left reading in bed, he was found to have died. It is not conceivable that Wheatley had any enemies. The universal respect with which he was regarded was well illustrated by the large and representative attendance when he was laid to rest in the little parish churchyard of Bieton, near Shrewsbury, on March 7th. Dr. Wheatley was in his sixty-fifth year; he leaves a widow and one daughter.

### HENRY WILLIAM LANGLEY BROWNE, O.B.E.,

LL.D., M.D., F.R.C.S.ED.,

Chairman of Council, British Medical Association, 1905-07.

We have to announce, with deep regret, the death of Dr. H. W. Langley Browne, which took place at his residence near Edgbaston, Birmingham, on March 7th. Dr. Langley Browne, who was in his eightieth year, died of acute bronchitis after an illness lasting only three days, but for the past seven years he had been an invalid as the result of an accident which caused the loss of his sight.

Henry William Langley Browne was the eldest son of a medical practitioner, the late Dr. Benjamin S. Browne, and was born at Bishop Auckland in the county of Durham in 1848, and was educated at Sydenham College and Birmingham General Hospital. He obtained the diplomas of M.R.C.S.Eng. in 1870, L.R.C.P.Ed. a year later, and F.R.C.S.ED. in 1882. He graduated M.B., B.Ch. Birm. in 1901, and proceeded to the degree of M.D. in the following year.

Dr. Langley Browne spent the greater part of his life in the town of West Bromwich, where he practised for fifty years—from 1870 to 1920. He was honorary surgeon to the West Bromwich Hospital from 1871 to 1904, and later became consulting surgeon. In the affairs of his profession he played a considerable part throughout his life, being prominent also in civic affairs. He held many offices in the British Medical Association.

In 1889 he served as chairman of the Section of Pathology organized by the Birmingham Branch; in 1891 he was elected to the Branch Council, and in 1894 became president of the Branch. Ten years later he was elected chairman of the West Bromwich Division, and in 1907 was appointed by that constituency to membership of the Representative Body. He was Chairman of the Council of the Association in the period 1905-07, after serving as a member of the central Council from 1899. At the Leicester Meeting in 1905 he was president of the Section of Industrial Hygiene and Diseases of Occupation. In the following year, when the Annual Meeting of the Association took place in Toronto, the University of that city conferred upon Dr. Langley Browne the honorary degree of LL.D.

Some indication of the place which he held in the estimation of his fellow practitioners throughout the country may be gained from the fact that when, in 1906, he became a candidate for the General Medical Council as a direct representative for England and Wales, he was returned at the head of the poll, and in 1911, when he sought re-election, this experience was repeated. He retired from the General Medical Council at the end of 1919, when

H. W. LANGLEY BROWNE, M.D.

[Elliott and Fry.

the officership of the Order of the British Empire was conferred upon him in recognition of his services within and without that body.

Dr. Langley Browne was a life member of the court of governors of the University of Birmingham. The members of the Midland Medical Society elected him as their president in 1902, and he was chosen to fill a similar office by the Association of Factory Surgeons in 1905. During the late war he was a member of the Central Medical War Committee, and also served on the staff of the West Bromwich Red Cross Hospital. His contributions to medical journals bore witness to a wide range of interest in his profession.

Municipal affairs attracted his attention, and as a member of West Bromwich Town Council for many years he was chairman, successively, of the sanitary and public libraries committee. He was also a justice of the peace for the county of Stafford, and a member of the County Territorial Association at one time. Among his recreations golf took a foremost place, and he was one of the founders and the first secretary of Sandwell Park Golf Club.

It is of especial interest to those at headquarters to recall that in 1906, when Dr. Langley Browne was Chairman of Council of the British Medical Association, he took a leading part in the establishment of the staff superannuation fund, and entertained the members of the permanent staff, administrative and executive, to dinner in the Hotel Cecil.

#### CHARLES HAROLD BLOXSOME, L.R.C.P. AND S.Ed., Fairford, Glos.

THE death occurred at Fairford, Gloucestershire, on February 17th, of Dr. Charles Harold Bloxsome, aged 70. He received his medical education at Manchester, and after taking the diplomas of L.R.C.P., L.R.C.S., and L.M.Ed. in 1880, held the post of house-surgeon at the Manchester Royal Infirmary. A year or two later he settled in practice at Fairford and became one of the surgeons at the cottage hospital. An enthusiastic bacteriologist, and devoted disciple of Lister, he carried out the Listerian technique with scrupulous care, and in the course of a few years built up a considerable surgical practice. His case-books show that many of his operations would come under the category of major operations.

One operation, though not of this character, is worth recording. On June 25th, 1887, he admitted into the cottage hospital a journeyman butcher, aged 67, with an enormously swollen left arm; on the anterior surface of the forearm were four hard, purplish-black eschars. Having examined some of the fluid from these and identified what he believed to be anthrax bacilli, and further hearing that the man had recently skinned and cut up a bull that had died in suspicious circumstances, Dr. Bloxsome excised and cauterized the lesions. The man stood the operation well, but died the following day. Dr. Bloxsome reported this to the authorities as a death from anthrax, and the case became at once notorious in the district. The editor of the local paper published an article with a view to proving that a young and inexperienced doctor had made the foolish mistake of labelling an ordinary case of blood poisoning as one of anthrax. The owner of the dead bull wrote in the same strain, and attacked the doctor for not publicly writing to the paper to explain how he had come to make so extraordinary an error. Dr. John Hitchman, a distinguished pathologist, took up the cudgels in Dr. Bloxsome's favour, having had an opportunity of examining the fluid which Dr. Bloxsome had removed and having seen the bacillus in the fluid. A fierce controversy ensued, but in the meantime Dr. Bloxsome had sent all his preparations and preserved tissue, with a full history of the case, to Mr. Wntson Cheyne, who reported that there could be no doubt that the patient died of anthrax. This appears to have terminated what was certainly an awkward episode in the life of a young medical man who had but recently settled in the district. In a very short time his worth was recognized, and he soon had as much work as he wanted. As a surgeon with a limited field at his disposal, he con-

until within a few weeks of his death. His love for bacteriology never waned; he used, apparently with great success, auto-vaccines prepared by himself in appropriate cases. Apart from his work he had many other interests. As a young man he was a great lover of horses and hunting, he was an expert on throwing a fly, he derived intense pleasure from music, but perhaps he enjoyed most of all a heated discussion on some debatable point with two or three chosen friends. His only son is carrying on the practice at Fairford. His second wife, with her daughter, survives him. The very large number of friends, both rich and poor, who attended a memorial service on February 21st at Fairford Church amply testified to the esteem in which he was held.

#### THE LATE SIR ROBERT PORTER, K.C.B.

WE are indebted to Sir ANTHONY A. BOWLEY, Bt., K.C.B., K.C.M.G., K.C.V.O., for the following appreciation of the late Major-General Sir Robert Porter, K.C.B., A.M.S. (retired).

I should like to add a few words to the obituary notice of Sir Robert Porter in your last issue, for he was always very keen to co-operate with the civilian surgeons in his command, and to avail himself in every way of their services. It was in the early days of the first battle of Ypres, on October 15th, 1914, that I first met Porter at a casualty clearing station established in Bethune in a large girls' school. He had just been promoted a surgeon general for services in the field, and was D.M.S. of the second corps, and he now was very anxious about his wounded, who came in increasing numbers, and were far too numerous in proportion to surgical equipment or personnel; whilst to add to our difficulties an enemy shell had just set alight a house opposite to the small civil hospital in which were some of our most severely wounded men. From that day until he left France at the end of 1917 I was constantly associated with Porter, for until May, 1915, I was the only consulting surgeon at the front, and it was with Porter's active co-operation and support that the first steps were taken to expand and convert the casualty clearing stations so as to make them efficient front-line hospitals. From that time onward he took the deepest interest in the surgery of the front, and did everything in his power to promote the improvement in the surgical staffs. It is indeed impossible to over-estimate the value of his constant support in our efforts to help the civilian surgeons in their work, and it is interesting to recall that No. 10 Casualty Clearing Station at Rémy siding, so well known to many of us, was the first casualty clearing station to be established in tents in the open country, instead of in various buildings, as was the custom in the earlier days of the war. Early in 1915 the British Expeditionary Force became divided into two "armies," and from that time Porter was continuously associated with General Plumer's Second Army, an army which was always a favourite with British officers and men alike. To the efficiency of this army Porter contributed very largely, for he was tireless in visiting every unit at the front, and was always accessible to his officers and ready to discuss any proposals for improvement in the conditions of the troops. The fact is that Porter took the greatest possible interest in the British soldier, and was out to help him in his difficulties and to ease his heavy burden in the horrible conditions of the Ypres salient. Few people knew how deeply they were indebted to him, for he was a silent and very modest man, whose motto might well have been "Deeds, not words." He was a true friend to the British soldier and a staunch supporter of every surgical improvement which might help his wounded men.

We regret to announce the death of Dr. J. W. KEIOHLEY of Blackburn, aged 61 years. He was a native of Blackburn and studied medicine at the University of Edinburgh and the London Hospital. He graduated M.B., C.M.Ed. in 1894, and proceeded M.D. in 1918. He took great interest in the work of the British Medical Association, was a member of the Executive Committee of the Blackburn Division for 1917-18, vice-chairman of the Division in 1919, and chairman in 1920. He represented the Blackburn Division in the Representative Body for

1925-27, and was a member of the Lancashire and Cheshire Branch Council for 1926-27. He was president of the Blackburn and District Medical Society in 1919, and was honorary secretary of the Local Medical and Panel Committee from its inception until three years ago. He had been a member of the Blackburn Town Council since 1907, was appointed vice-chairman of the town hall and public baths committee in 1920, and two years later became chairman of the committee. In February, 1923, he was elected an alderman. He was placed on the Commission of the Peace for the borough in 1920. He served on most of the corporation committees, and was the representative of the town council on the Lancashire Asylums Board for nine years. During the war Dr. Keighley did a large amount of voluntary work for his fellow practitioners on war service, and was an active member of the Belgian refugees subcommittee. Dr. Keighley had presided over a meeting of the town hall committee on the afternoon of February 13th, and owing to indisposition he was prevented from attending a meeting of the Central Conservative Club in the evening; he died on February 15th. He is survived by his widow, three sons, and a daughter; one of the sons is a member of the medical profession in Blackburn, where his son-in-law is also in practice. A colleague writes: Dr. Keighley was ever a loyal colleague and friend, and, in his quiet and unassuming way, was always ready to do a good turn for any deserving person or cause. His sudden death caused deep sorrow to his medical brethren and his colleagues on the town council. He was a man of the highest principle, modest, unassuming, and quietly genial in all his relations with his colleagues and his fellow workers on the public bodies on which he served. His life was a full one, and he could always be relied on for punctual attendance. At a solemn requiem mass, prior to the interment on February 20th, the Rev. Father Singleton, rector, concluded a moving address by saying that Dr. Keighley never became a cynic; he mixed in public life, yet he was not soiled. An uncharitable word never came from his lips. He made no distinction between rich and poor, giving to both the same wonderful and undivided attention. His name was held in high esteem and regard among the poor, and, after all, that was one of the true tests of greatness and goodness.

Dr. ARTHUR STOPFORD UNDERHILL died peacefully in his sleep on February 20th, at his residence in Barnes, in his seventy-ninth year. He belonged to a medical family, well known and honoured for over a century at Great Bridge, Tipton, and West Bromwich. He was a native of Tipton, and received his medical education at Trinity College, Dublin, where he graduated B.A., M.B., M.Ch. in 1870, at the age of 21. Dr. Underhill obtained the diploma M.R.C.S.Eng. in 1872, the D.P.H. Camb. in 1875, and proceeded M.D. in 1877. After holding the appointments of resident physician and medical tutor at Queen's Hospital, Birmingham, and resident medical officer at Birmingham Children's Hospital, he succeeded quite early to his father's large general and consulting practice, and was medical officer of health for Tipton for fifty-two years, retiring from that office only two years ago. He served as medical superintendent, West Bromwich Union Infirmary, and held office for a term as president of the Birmingham and Midland Counties Branch of the Society of Medical Officers of Health. He was a lifelong member of the British Medical Association. "J. A. S." writes: Dr. Underhill's chief interest lay undoubtedly in consultative surgical and medical practice. Gifted with a commanding presence and ability to lead, he was bound to succeed. He was a man of the highest integrity and of unbounded generosity. For over fifty years he was first surgeon and then consulting surgeon to the Gnest Hospital, Dudley. As an illustration of his careful nature it may be mentioned that he made a practice of reading up, whenever possible, all the steps of any major operation he contemplated doing on the morrow. He reasoned carefully with patients respecting an operation without any attempt to force surgical procedure on them. I have so often known him to discuss it with me as the only fair and equitable thing to do, and he emphasized the necessity for

putting himself in the patient's place. His opinion was largely sought by his colleagues. On Sunday he practically kept open house, and at any meal after breakfast it was quite problematical whether we sat down ten, or even twenty. Dr. Underhill was twice married, first to Mary Symons, daughter of Major-General C. B. Symons, by whom he had four daughters and three sons, and secondly, to Lucy Cory, sister of the vicar of Tipton. He was buried at Tipton on February 24th, in the presence of a large number of friends.

Mr. GERALD SICHEL, who died at Sevenoaks on February 29th, received his medical education at Guy's Hospital. He obtained the diplomas M.R.C.S., L.R.C.P. in 1892, and the F.R.C.S.Eng. two years later. He held various resident posts, and after serving for some years as surgeon in the Royal Navy was for a time in charge of the light department at Guy's Hospital. He entered the navy as surgeon in November, 1894. He served in H.M.S. *Gibraltar* at the Cape from 1896 to 1899, when he was appointed an instructor at the Naval Medical School at Haslar. He resigned from the navy in 1903. He was the author of a small work, *Ambulance Notes*, which was adopted by the Admiralty. During the great war he held a commission as major in the R.A.M.C., when he acted as chief surgeon to the Lord Derby War Hospital, Warrington; he was also surgical specialist both at home and with the British Expeditionary Force, being mentioned in dispatches. In civil life he held the post of surgeon to the Sevenoaks and Holmesdale Hospital, and the Sevenoaks Hospital for Children with Hip Disease; he was also consulting surgeon to Sevenoaks Grammar School. Mr. Sichel was an active member of the Sevenoaks Division of the British Medical Association, and had acted as representative of the Guildford Division at the Annual Representative Meeting in London in 1906. "C. A. H. P." writes: It was only on August 24th that I went down to Sevenoaks to give an anaesthetic for him, and within half an hour of my leaving his house he was called out to help at the scene of the terrible accident on the railway at Riverhead. Here he directed operations and toiled ceaselessly for many hours; he shouldered great cares and anxieties for several days, looking after a number of patients in the Sevenoaks and Holmesdale Cottage Hospital. I saw him several times after that occasion in August, as he always kept open house at his charming residence. He had not been so well the last year or so, but there appeared to be no reason why he should not carry on. He had personal anxieties for some years which had aged him prematurely, but it was not until just lately that he was considered in any danger. His death creates a gap that it will be impossible to fill. As a colleague he was delightful to work with; as a surgeon he was most careful and painstaking, able and efficient, shrewd and careful in judgment. He never operated for the sake of operating; he always chose the safest and wisest course for the patient, and avoided experimenting. Much sympathy is felt for his younger daughter, who had been his constant companion and right-hand "man" in recent years, and for his other relatives.

Dr. WILLIAM HERBERT LISTER MARRINER, who died at Bournemouth on February 27th, at the age of 69, received his medical education at St. Thomas's Hospital, London. He graduated M.B.Lond. in 1884, obtaining the diplomas M.R.C.S.Eng. and L.S.A. in the same year. After a period as clinical assistant in St. Thomas's Hospital he commenced practice in Bournemouth, subsequently becoming attached to the staff of the Royal Victoria and West Hants Hospital there. In this institution he held, at the time of his death, the appointment of consulting surgeon for diseases of the nose, throat, and ear. Dr. Marriner took an active part in local professional affairs. He was one of the earliest members of the Bournemouth Medical Society, and served for a term as president. He was a member of the Executive Committee of the Bournemouth Division of the British Medical Association in 1906-07 and 1909-10, vice-chairman in 1912-13, and chairman in 1914. He was vice-president of the Dorset and West Hants Branch in 1908,

and a member of the Branch Council 1911-15. He is survived by his widow, one daughter, and two sons, the younger of whom is in the medical profession. A colleague writes: I remember Marrinor on his first coming to Bournemouth. For some time he was in general practice, but afterwards he devoted himself to the Victoria Hospital. He was a keen Volunteer officer for many years. He took an interest in public affairs and in politics, but was not an active participant. His chief characteristic perhaps was his great loyalty to his friends, his hospital, and his regiment.

Dr. WALTER RIGDEN, who died on February 28th at Bournemouth, in his 80th year, was the last survivor of the five sons of the late Dr. George Rigden of Canterbury, of whom four were in the medical profession. After studying medicine at University College Hospital he became M.R.C.S. and L.S.A. in 1870, and graduated M.D.St. Andrews in 1892. Dr. Rigden had been for over fifty years a well-known figure in South Kensington. He practised, until his retirement a few years ago, nearly opposite Brompton Oratory, and had witnessed much of the transformation of South-west London since the sixties. Among his recollections of olden days were those of disorderly scenes at the long extinct Cremorne Gardens (where the big generating station for the electric railways now stands), much frequented by rowdy elements sixty or seventy years since. Dr. Rigden was local honorary secretary for Epsom College for a great number of years, and, in fact, resigned this position only two years ago. He was a loyal and valued member of the council of the Medical Defence Union almost from the foundation of that body. He had also been a member for close on half a century of the Brompton Medical Book Club, and was an old member of the British Medical Association. Dr. Rigden was very highly esteemed by a wide circle, both of professional colleagues and of patients. He was a man whose complete uprightness was transparent to all, and he was always more than ready to do a kind act or help with wise counsel the younger men in his profession. He was twice married, but leaves no family.

Dr. WILLIAM JOHN CUTHBERT WARD, who died at Harrogate at the age of 83 on February 16th, received his medical education at Edinburgh; he obtained the diplomas: L.R.C.P., L.R.C.S.Ed. in 1868, and the M.R.C.S.Eng. in the same year. After practising for some time in London, he went to Harrogate in 1877, and for thirty years held the post of medical officer of health, retiring when a whole-time appointment was created. For forty years he was surgeon to the Harrogate section of the London and North-Eastern Railway, and medical officer to the Ancient Order of Foresters. His wife predeceased him in 1924; he leaves five sons and four daughters, two sons being in the medical profession.

Dr. THOMAS FAIR HETHERINGTON SPENCE, who died at Peebles on February 20th, was the eldest surviving son of the late Dr. James Spence, professor of surgery in the University of Edinburgh. Dr. Thomas Spence received his early education at Edinburgh Academy, graduated M.B., C.M. at Edinburgh University in 1875, and afterwards acted as house-surgeon to his father. After a period of post-graduate study spent in Vienna he became for a time assistant to his father in the department of surgery, and then settled in general practice in Edinburgh, where he was much beloved by his patients for his kindness of heart. He retired from practice nearly twenty years ago, and went to reside at Innerleithen. Both on Tweedside and at Loch Leven he was a noted angler, and his little book entitled *How to Catch Trout* went through many editions. Dr. Spence is survived by his widow.

Dr. DAVID ROBERTSON DORIE died at Digby, Lincolnshire, on February 22nd, a fortnight after retiring from practice in Crieff. He was born at Ladykirk and was educated at George Watson's College and the University of Edinburgh,

where he graduated M.B., C.M. in 1882, proceeding M.D. three years later. He obtained the diplomas F.R.C.S.Ed. in 1902 and the D.P.H. in 1906. After graduation he spent periods of medical service in Greenock, Cromarty, and Coldstream, and for the past twenty-seven years he had carried on a large practice in Crieff, where he was held in great respect by a wide circle of patients and friends. We mentioned on February 18th (p. 291) a presentation made to him in connexion with his retirement from practice. He had been medical officer of health for Coldstream, and afterwards, while residing in Crieff, he acted in a similar capacity for the burgh of Auchterarder, and took an active part in the establishment of Crieff and District Cottage Hospital. He had had twenty-five years' service in the R.A.M.C. He published articles on typhoid fever carriers and on acute yellow atrophy of the liver. He is survived by a widow, one son, and two married daughters.

Dr. ALEXANDER STUART of Crieff, who recently died, studied medicine at the University of Edinburgh, where he graduated M.B., C.M. in 1892, and obtained the diploma of L.R.C.S.; he proceeded M.D. in 1913. Dr. Stuart was a district parochial medical officer and public vaccinator, honorary medical officer of Crieff and District Cottage Hospital, and medical officer of the post office. His constant unselfishness and devotion to his patients rendered him widely popular in the district. He was a member of the British Medical Association.

## Medical News.

THE Robert Jones Medal and Association Prize for 1927 has been awarded by the British Orthopaedic Association to Mr. J. F. Brailford for an essay on deformities of the lumbo-sacral region of the spine.

Dr. E. GRAHAM LITTLE, M.P., will give an address on the future of medical practice—intended more especially for senior students and young practitioners—at a meeting arranged by the Metropolitan Counties Branch of the British Medical Association, to be held at the B.M.A. House, Tavistock Square, London, on Thursday, March 22nd, at 5.30 p.m. Tea and coffee will be served at 5 o'clock. All fourth and fifth year medical students and recently qualified practitioners are cordially invited.

At the meeting of the Royal Anthropological Institute to be held at 52, Upper Bedford Place, W.C.1, on Tuesday, March 27th, at 8.30 p.m., Sir Arthur Keith, M.D., F.R.S., will give a lecture, illustrated by lantern slides, on the human remains discovered by Sir Aurel Stein in ancient cemeteries of the Taklamakan Desert.

A PROVINCIAL meeting of the Tuberculosis Society and the Society of Superintendents of Tuberculosis Institutions is to be held in the Dunn Laboratory, Oxford, on Thursday, Friday, and Saturday, March 29th, 30th, and 31st. At 2 p.m. on the first day there will be a discussion on lupus and its treatment, under the chairmanship of Sir Farquhar Buzzard. Two discussions will be held on March 30th: on the potentially tuberculous child, at 10 a.m., with Sir St. Clair Thomson in the chair, and on the treatment of haemoptysis in pulmonary tuberculosis, at 2 p.m., with Professor Lyle Cummins in the chair. The concluding session, on Saturday morning, will be devoted to intestinal tuberculosis, under the chairmanship of Dr. F. R. Walters. The two participating societies will hold their annual meetings at the Clarendon Hotel on the evening of March 29th, and a dinner will be held on the following evening. Non-members who are interested in the subjects of the programme will be welcomed as visitors. The joint honorary secretaries are Dr. J. R. Dingley (Darvill Hall Sanatorium, Robertsbridge, Sussex) and Dr. G. T. Herbert (Tuberculosis Department, St. Thomas's Hospital, S.E.1).

THE Fellowship of Medicine announces that Professor Frederick Lanjeard will lecture at the Medical Society of London, 11, Chandos Street, on dull and backward children, on March 19th, at 5 p.m. On March 22nd Professor Louise McIlroy will give a lecture-demonstration at the Royal Free Hospital at 5 p.m., and on the same date, but at 6.30 p.m., Mr. Theodore Just will give a demonstration at the Golden Square Throat Hospital. The lectures and the demonstrations are the last of the series arranged by the Fellowship of Medicine for this session, and are free to medical practitioners. A week's course at the Brompton Hospital for Consumption

and Diseases of the Chest begins on March 19th. At the Royal National Orthopaedic Hospital there will be an all-day course from March 15th to 31st, and from March 19th until the 30th the Hampstead General Hospital will provide a late afternoon course, including demonstrations or short lectures in medicine, surgery, and the specialties. There will be no special courses between March 31st and April 16th, but the Fellowship provides a general course of instruction at its affiliated hospitals throughout the year, comprehensive tickets being issued for any period from one week to one year, and special arrangements being made for those limited to part-time work. Full particulars of this course, syllabuses, and specimen copies of the *Post-Graduate Medical Journal* may be obtained from the secretary of the Fellowship, 1, Wimpole Street, W.1.

THE London School of Hygiene and Tropical Medicine is arranging courses in tropical hygiene for laymen as well as for medical practitioners. Inquiries should be addressed to the secretary of the School, Malet Street, W.C.1.

THE congress of the Royal Sanitary Institute at Plymouth, from July 16th to the 21st next, will comprise seven sections—namely, sanitary science and preventive medicine, engineering and architecture, maternity and child welfare, including school hygiene, personal and domestic hygiene, hygiene of food, hygiene in industry, and veterinary hygiene. In connexion with the congress there will be conferences of representatives of sanitary authorities, port sanitary authorities, national health insurance services, medical officers of health, engineers and surveyors, sanitary inspectors, and health visitors. Further information may be obtained from the secretary, the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.1.

THE 155th anniversary dinner of the Medical Society of London was held at the Grosvenor on March 8th, with the president, Mr. Herbert W. Carson, in the chair. The toast of the society was proposed in a genial speech by Lord Carson, who declared that no one owed more than he did to the medical profession, but, gratefully as he admired doctors, he had seldom seen them at their best as witnesses in courts of law. A difficult problem before both professions was to find a satisfactory definition of lunacy which went further than merely saying that a lunatic was a person of unsound mind. The president, in his reply, spoke of some of his great predecessors in office, and congratulated Dr. Poynton on this year's Lettsomian Lectures. The society, he said, was in a most flourishing condition, 101 new Fellows having joined it in the past year, and the average attendance at the meetings held this session was nearly seventy. The health of the visitors was proposed by Sir John Ross Bradford, who said that the well-merited success of the society depended on its activity in promoting clinical medicine and surgery, and in providing opportunities for medical men to meet one another, sometimes as hosts and sometimes as guests. Surgeon Vice-Admiral Gaskell, in his reply, spoke of the enormous help given by the heads of the civil profession to the Royal Naval Medical Service, and Dr. F. G. Crookshank also responded to the toast in a very entertaining speech.

THE Lord Mayor of London presided over the annual general meeting of St. Mark's Hospital, City Road, at the Mansion House on March 8th. It was stated that since the middle of the last century every Lord Mayor in turn—except one—had been president of the hospital. Sir Charles Batho said that last year was eventful in the hospital's history in consequence of the completion and opening of the new wing. With this enlargement the number of beds had been increased to seventy-two, and an up-to-date cancer research laboratory had been provided. Last year 583 in-patients had been admitted, and the attendance of out-patients (6,440) had been the largest in the hospital's history. He added that St. Mark's was the only entirely free hospital of its type in the world; surgeons came from every part of the world to study its methods of treating diseases of the rectum. Unfortunately there was a balance on the wrong side this year, with an excess of expenditure over income of nearly £700, and a debt of £3,500 on the new wing. The Lord Mayor spoke very highly of the work of the hospital, and said he proposed to pay a visit to it in the course of his year of office, and to bring the sheriffs with him. The Corporation of the City of London had been glad to assist this deserving charity, and would no doubt help it again.

THE March issue of the *Edinburgh Medical Journal* is devoted to tuberculosis, and contains several interesting clinical and pathological articles. Professor Murray Lyon contributes a careful critical account of the use of sacrocrystin, summing up on the whole in favour of this form of treatment. Dr. Donald Stewart deals with the examination of the cerebro-spinal fluid in tuberculous meningitis for diagnostic purposes. A report is given of the discussion on ultra-violet therapy arranged by the Medico-Chirurgical Society of Edinburgh last December.

DR. BRIAN B. METCALFE has been returned unopposed to the Cornwall County Council as the member for the Liskeard Division. Dr. Metcalfe is also a member of the Cornwall County Council Committee and chairman of the South-East Cornwall Division of the British Medical Association.

AT the invitation of the Board of Management of the London Lock Hospital the Minister of Health has appointed a committee to inquire into the administration of the hospital, consisting of the Rt. Hon. Sir John Eldon Bankes (chairman), Dr. John Fawcett, and Mrs. H. J. Tennant. The terms of reference are: To inquire into the management, administration, and staffing of the London Lock Hospital, with special reference to the arrangements for the medical treatment of the patients and to the provision made for the moral, social, and material welfare of the inmates. The proceedings of the committee will be held in private.

WE are asked to state that hospitals situated within eleven miles of St. Paul's desiring to participate in the grants made by King Edward's Hospital Fund for London for the year 1928 must make application before March 31st to the honorary secretaries of the Fund at 7, Walbrook, E.C.4. Applications will also be considered from convalescent homes which are situated within the above area, or which, being situated outside, take a large proportion of patients from London.

THE National Union of Students of the Universities and University Colleges of England and Wales is seeking to secure hospitality in Great Britain for foreign students who are anxious to improve their knowledge of English and who are prepared, in exchange, to give their services as teachers of their own languages. Applications for hospitality for varying periods from Easter onwards have been received from a number of French and German students, all possessing satisfactory credentials, and those interested are asked to communicate with the secretary for Exchange and Tuition Visits, National Union of Students, 3, Euston Square, London, W.C.1.

LADY HUDSON has given a donation of £3,000 to the Westminster Hospital for the perpetual endowment of a ward in memory of the late Sir Robert Hudson, who was treasurer of the institution from 1921 till 1927.

ON behalf of *The British Journal of Cambridge University Press* will shortly on *The Development of the Human Eye* by with a preface by Sir John Herbert Parsons and reproductions of 250 original drawings by the author.

WE have received the first issue, dated January, 1928, of *Levante Medico*, a monthly journal published at Murcia in Spain under the editorship of Dr. Juan Antonio Martínez Ladrón de Guevara, assisted by Drs. Fidel Fernández Martínez and Ramón Sánchez Parra. The issue contains original articles on idiopathic cutaneous atrophy by Drs. Barrio de Medina and Nicolás Calvin, a study of rabies by Dr. Ladrón de Guevara, the prophylaxis of trachoma in Murcia by Dr. Eduardo Poveda Pagan, society intelligence, and medical news.

ACCORDING to the returns received from thirty-seven States scarlet fever in the United States of America was more prevalent in 1927 (158,978 cases) than in 1926 (143,159 cases) or in 1925 (135,937 cases).

PROFESSOR JOLLY, who holds the chair of histophysiology at the Collège de France, and is the author of a well-known textbook on haematological technique, has been elected a member of the Académie de Médecine.

DR. ALFONS JACOB, lecturer in psychiatry at Hamburg, has been invited by the Brazilian Government to undertake the establishment of an institute for the study of the anatomy of the brain at Rio de Janeiro, and to deliver a course of lectures on nervous and mental diseases from May to July.

THE second congress of the French societies of oto-neuro-ophthalmology will be held at Marseilles from May 25th to 27th. Papers will be read on vascular spasm by Drs. Breiner of Brussels, Aubaret and Sedan of Marseilles, and Portmann of Bordeaux. Further information can be obtained from the general secretary, Dr. Velter, 38 Avenue du Président Wilson, Paris XVI.

THE eighth congress of the Italian society of medical radiology will be held at Florence from May 14th to 16th. Further information can be obtained from Dr. Manlio Gambillo, Istituto di radiologia della R. Università, Via degli Affari 33, Florence.

THE following appointments have recently been made in foreign medical facilities: Dr. Georges Fontès, professor of biological chemistry at Strasbourg; Dr. Hans Reinhard Schmidt of Bonn, professor of obstetrics and gynaecology at Düsseldorf; Dr. Rudolf Klapp of Berlin, professor of surgery at Marburg; Dr. Arnt Kohlrausch of Greifswald, professor of pathology at Tübingen.

## An Address

ON

## SOME ASPECTS OF GALL-BLADDER DISEASE.

DELIVERED TO THE Ayrshire Division of the BRITISH MEDICAL ASSOCIATION, NOVEMBER, 1927,\*

BY

D. P. D. WILKIE, M.Ch., F.R.C.S.,  
PROFESSOR OF SURGERY, UNIVERSITY OF EDINBURGH.

(With Special Plate.)

DURING the past few years the importance of gall-bladder disease has become more and more fully recognized. There is still, however, a widespread belief that gall-stones constitute the important, if not the essential, element in such disease, and a clinical diagnosis of cholecystitis is confined by many to those acute attacks of obstructive cholecystitis which are apt to supervene when a gall-stone becomes impacted in the cystic duct or the neck of the gall-bladder. Many years ago Moynihan drew attention to a group of symptoms which he termed the inaugural symptoms of gall-stones. These symptoms—flatulence, nausea, epigastric discomfort, etc.—he showed were frequently present for a long period before attacks of colic proclaimed in classical terms the presence of one or more calculi. We now know that these inaugural symptoms are those of chronic cholecystitis, which may or may not go on to stone formation.

Gall-stones are so common, so many people harbour them for years and die with them, without apparently suffering any very serious trouble, that many medical men are inclined to regard lightly such evidence of biliary disease, and to encourage an expectant attitude unless intolerable attacks of colic render a patient's life a burden.

The more I see of biliary disease, the more convinced I become that it is practically never harmless, and that, after years of bearable discomfort, many patients eventually succumb from disease which is either directly or indirectly due to long-standing biliary infection. This is particularly true of patients in comfortable financial circumstances, for they tend to spend years in trying "cures" which those of the hospital class, fortunately for themselves, cannot afford. It is only right to state that the responsibility for the failure to deal in a timely or an adequate manner with this common disease rests mainly with those whose duty it is to teach the medical undergraduate. Such conflicting views have been expressed, not only in regard to the frequency and importance of the condition, but also in regard to the nature of the infection, that no clear picture of the disease is held, and uncertainty here, as elsewhere, leads to capriciousness, and thus to indefinite delay.

## NATURE OF GALL-BLADDER INFECTIONS.

Certain organisms can grow in bile, notably the *Bacillus coli* and the typhoid bacillus. These two organisms have, on many occasions, been recovered from inflamed gall-bladders, particularly during acute attacks, and there is still a widely prevalent belief that one or other of them plays the leading part in the etiology of cholecystitis. This view, which I hope to show is entirely erroneous, has encouraged the belief that agents which stimulate a flow of bile to wash out the gall-bladder, or are excreted in the bile and may possibly disinfect it, are of value in the treatment of cholecystitis.

It is now some years since Rosenow reported his remarkable series of observations and experiments on cholecystitis. From the walls of a large number of diseased gall-bladders he was able to cultivate a streptococcus which, on injection into animals, appeared to have a selective affinity for the gall-bladder. Rosenow's results were received with scepticism, and many authorities, failing to find in the bile or in portions of the walls of obviously diseased gall-bladders the streptococcus which he described, disregarded his work, and have based their opinions and their teaching

on the types of organism which they have, in their own experience, been able to cultivate in cholecystitis cases. It is a significant fact, however, that so many observers have failed to grow any bacteria from either the bile or the gall-bladder wall in a large proportion of their cases of cholecystitis.

In my own experience I was impressed by the fact that, whilst the bile and gall-bladder wall proved so often to be sterile on culture, yet stained sections of the wall revealed the presence of streptococci in the submucous coat. There evidently was present an intramural infection by a streptococcus which did not grow readily on most media.

Illingworth, working in my clinic, was able to show that, using Rosenow's special medium, streptococci could be grown from the wall of the gall-bladder in quite a large percentage of cases in which the bile was sterile. He further showed that organisms of the *coli* group are relatively infrequent except in acute suppurative cases.

This work has been carried a step further by Dr. A. L. Wilkie, who has shown that cholecystitis is almost invariably an intramural streptococcal infection, and that Rosenow's contention of a selective affinity of this organism for the gall-bladder in experimental animals is strikingly true. Wilkie has shown that in over 85 per cent. of cases of chronic cholecystitis, usually associated with gall-stones, the streptococcus can be recovered in pure culture from the cystic lymph gland through which the lymph from the gall-bladder drains. In a smaller percentage of cases he has grown the same organism from the submucous coats\* of the gall-bladder if no bile has been allowed to come in contact with the tissue taken for culture. He has brought to light the illuminating and remarkable fact that bile inhibits the growth of this streptococcus. Hence, when a clipping of the whole thickness of the gall-bladder wall is taken for culture, the bile adhering to the mucous coat prevents the growth of the streptococcus present in the submucosa. This fact accounts for the widespread failure to confirm Rosenow's findings.

Even Judd, working under the most favourable conditions, got a positive result in cultures of the gall-bladder wall in only 29 out of 100 cases, and in only 5 out of 22 specimens of strawberry gall-bladder. In only 7 per cent. of his cases of cholecystitis was a positive culture obtained from the bile (3 streptococci, 3 spore-bearing bacilli). In no case were typhoid bacilli found, although in 21 cases there was an antecedent history of typhoid fever. *B. coli* was conspicuous by its absence in the whole series. In only 2 cases out of 52 did Wilkie find the *B. coli*, and in both an acute obstructive cholecystitis was present. It was, therefore, probably a secondary infection.

Following the injection of a suspension of streptococci, obtained from a human gall-bladder, into the ear vein of a rabbit, Wilkie found that the animal developed a chronic progressive cholecystitis, whether the cystic duct was patent or was ligated. The organism evidently reaches the gall-bladder by the blood stream, causes an intramural infection, the bile remaining sterile, and from the gall-bladder wall the organisms are absorbed by the lymphatics. Hence the importance of the gall-bladder as a nidus of focal infection.

Medical treatment of cholecystitis, to be rational, therefore, must be aimed at this intramural streptococcus, attacking it through the blood stream—for example, by vaccine or by some agent which is absorbed by the gall-bladder and passes through its wall; but so far we know of no such agent. Drugs which merely disinfect the bile cannot be expected to have any real value, as the bile, in the vast majority of chronic cases, is sterile.

The necessity for surgical treatment in chronic cases becomes obvious, and this treatment should consist in removing the diseased wall where the infection is located, not merely in draining the lumen of the gall-bladder.

## RELATIONSHIP OF CHOLECYSTITIS TO GALL-STONES.

Whilst infection of the gall-bladder and gall-stones are usually found together, and whilst most evidence points to the infection as the primary factor, yet we have always

\* As Halpert has shown, the gall-bladder has no true submucous coat such as is found in the stomach and intestine. The term is used for convenience to indicate the coats outside the lining mucous membrane.

\* The address was illustrated with lantern slides

believed that there are two types of gall-stone which are metabolic in origin—namely, the single pure cholesterol stone and the multiple pure pigment calculi. The former, found often in an apparently normal gall-bladder, is apt to be associated clinically with intermittent afebrile attacks of biliary colic in an otherwise healthy individual; the latter, also found in a gall-bladder showing no patent signs of inflammatory disease, and due to excess of pigment in the bile, are also liable to cause colic, but no ill health.

In the light, however, of the work on the bacteriology of the gall-bladder quoted above we may have to revise our ideas as to the aseptic origin of both these types of stone. This much is certain, that in several cases with a single cholesterol stone and a very slightly thickened gall-bladder a streptococcus has been grown from the wall of the latter. Also, in one case of single cholesterol stone, Illingworth isolated a streptococcus from the centre of the calculus.

The origin of the multiple faceted calculi, of mixed cholesterol and bilirubin composition, probably dates from an acute attack of obstructive cholecystitis, when the cystic duct was occluded, either by a single cholesterol stone or merely by inflammatory oedema. The inflammatory exudate within the gall-bladder in such cases provides abundant material for the nuclei of stones, which, in their subsequent growth, reproduce in their strata the history of the successive steps in the gall-bladder pathology.

#### CHOLESTEROSIS AND THE MULTIPLE MULBERRY STONE.

Many surgeons, among whom Moynihan and W. J. Mayo were the first, have drawn attention to a curious condition of the mucous membrane of the gall-bladder in cases in which no gross disease was evident from without, where small white specks project from the villi, giving an appearance somewhat resembling the surface of a strawberry. This condition, which is not uncommon, has been found where no stones were present, but also in association with several, usually mulberry-shaped, calculi. Boyd has described, and has illustrated very beautifully, the nature of this lipid deposit in the cells of the mucosa of the gall-bladder and in the subepithelial layer, and has shown how small lipid-laden papillomata may form and possibly become shed off into the lumen of the organ. Mentzer has reported similar observations. Boyd believes that cholesterol is absorbed from the bile by the mucous membrane of the gall-bladder, and, when there is disease in the wall, the paths of absorption are partially obstructed and cholesterol esters accumulate in the cells of the mucous membrane and in those of the underlying stroma.

Our observations, in the many cases of cholesterosis of the gall-bladder which we have encountered, entirely confirm those of Boyd, and in several the various stages between punctiform lipid deposits, lipid-laden papillomata, and mulberry cholesterol calculi have been present in the same specimen. Illingworth has repeated Boyd's histological investigations (Figs. 1 to 6). Further, Wilkie has shown that in the submucosa and in the cystic gland in every case examined a streptococcus was present.

The multiple mulberry cholesterol stone is thus of septic origin, and the phases of its development are as follows:

1. Intramural streptococcal infection of the gall-bladder.
2. Lipoid accumulation in the mucosa and subepithelial layer.
3. Formation of lipid papillomata.
4. Shedding off of these to form the nuclei round which cholesterol is deposited.

#### THE CALCIUM STONE OF THE CLOSED GALL-BLADDER.

Occasionally we meet with cases where gall-stones composed mainly of calcium, in the form of carbonate, are shown up readily by x rays as dense shadows. In such cases it is found that the gall-bladder wall shows signs of chronic inflammation and that the cystic duct is obstructed (Figs. 7 and 8). In this connexion the experimental work of A. L. Wilkie is of interest. He found that in the cholecystitis produced in rabbits by intravenous injections of streptococci calculi were common. In cases where the

cystic duct was patent cholesterol was the main, if not the only, constituent; in those in which the cystic duct had been ligated calcium was the main constituent.

#### SYMPTOMATOLOGY OF CHOLECYSTITIS.

The onset of symptoms is so gradual that it is often very difficult for the patient to give a precise date to the beginning of the trouble. A tendency to flatulence coming on immediately after eating, often indeed during a meal, a feeling of constriction and oppression, causing a desire to loosen the clothing, a sense that the patient has eaten too much, even after a small meal—these symptoms, so common among the middle-aged female population, are, in the majority of instances, due to cholecystitis. A sense of nausea and desire to be sick, coming on at irregular times, sometimes accompanied by an aching under the right costal margin and in the right scapular region, an aggravation of these symptoms by any exposure to cold or chill, with, in many cases, the appearance of a faint tinge of yellow in the skin or a noticeable muddiness of the complexion, are symptoms often attributed to "liver," but due usually to a slight exacerbation of a chronic inflammatory process in the gall-bladder. Actual vomiting is not infrequent at such times, and articles of diet, such as potatoes and all fatty foods, are avoided as they are found to aggravate the discomforts from which the patient suffers. Sometimes the patient complains of flatulence, the onset of which is delayed for an hour after food, is accompanied by "acidity" with heartburn and waterbrash, and a gnawing epigastric pain, almost suggestive of duodenal ulcer, but differing in two respects—namely, in the comparative failure to get relief by eating more, and the absence of the periodicity so characteristic of ulcer.

It is, however, by no means easy in some cases in stout females to diagnose, from a clinical history and physical examination alone, duodenal ulcer from cholecystitis. Under the term "cholecysto-duodenal syndrome" I have described a clinical picture, almost indistinguishable from that of cholecystitis, which is presented by quite a large group of female patients suffering from duodenal ulcer. By special investigation, however, the two conditions can be readily and surely distinguished, even when both are present, which is by no means rare.

When definite attacks of colic have occurred, if they have been of the real agonizing type, one may be sure that one or more gall-stones are present. Attacks of colic simulating somewhat closely the true variety due to stone are, however, sometimes apparently caused by interference with the emptying of the gall-bladder, due to kinking at the neck. The removal of such a gall-bladder, which is always thickened but contains no stone, has, in numerous instances, led to a cessation of the colic-like attacks.

I need only mention the attacks of acute obstructive cholecystitis when, with acute pain accompanied by vomiting, a coated tongue, often some shivering and rise of temperature, with marked tenderness in the right hypochondrium and a catch in the breath, the picture of a stone impacted in the neck of the gall-bladder, which is inflamed and tensely distended, is clear and unmistakable. It is in these attacks that we get the secondary pulmonary signs of dullness with crepitations and even friction at the base of the right lung, due to the rigid right half of the diaphragm. These signs must be regarded as an integral part of the clinical picture of acute cholecystitis, and must not be allowed to divert attention from the true seat of infection. Examination of patients with the x-ray screen during such an acute attack has shown quite clearly an immobile right cupola of the diaphragm, with consequent impaired expansion at the lower lobe of the right lung.

The association of cholecystitis with appendicitis must ever be kept in mind. The two conditions in a chronic phase are frequently encountered together. I have on two occasions, however, had to deal with acute suppurative lesions of both appendix and gall-bladder, occurring simultaneously in the same patient. There is much to be said for the view that inflammatory disease of the appendix and gall-bladder represent not consecutive but simultaneous blood-borne infections, usually of streptococcal type.

## SPECIAL METHODS OF DIAGNOSIS.

*Use of the Duodenal Tube.*

Much was hoped from what is commonly known as the Meltzer-Lyon test, whereby bile is withdrawn from the duodenum by means of the duodenal tube after the introduction of magnesium sulphate. There can be no question that in cases of cholangitis and in advanced cholecystitis, particularly if the large septic type of stone be present, very definite and valuable information may thus be obtained. In quite a large proportion of cases of cholecystitis, however, we find at operation that the bile in the gall-bladder is normal in appearance and is sterile on culture, and, withdrawn by the duodenal tube, could not possibly have indicated the intramural infection present in the submucous layer of the gall-bladder. The results, reported by certain observers, of bile infected by *B. coli* being recovered by the duodenal tube in a large proportion of cases of cholecystitis, are quite out of keeping with our operative experience.

*Cholecystography.*

Since the introduction of pyelography in the diagnosis of renal disease there has been no advance so striking or so helpful in visceral diagnosis as the method devised and elaborated by Graham and Cole of obtaining shadow-graphs of the gall-bladder by the use of an opaque dye. Whether the dye be given intravenously or by the mouth the results, if interpreted intelligently, are of the greatest help in diagnosis. If a dose of not more than 3 grams intravenously, or 4.5 grams by the mouth, be used, no untoward effects are produced, and the functional capacity of the gall-bladder can be gauged with a fair degree of accuracy.

From an experience of more than 200 cases I can state without hesitation that it transcends all other methods of diagnosis, and gives reliable data in over 90 per cent. of cases. It is of especial value if used in conjunction with a barium meal, as recommended by Dr. Woodburn Morison, for then it may, as it has done in five of my cases, reveal a normal gall-bladder and a deformed duodenal cap in a patient presenting the cholecysto-duodenal syndrome.

The dye test is seen to greatest advantage in cases where cholesterol calculi are present in a gall-bladder with patent cystic duct. Then the negative shadows cast by the calculi enable not only a positive diagnosis of gall-stones to be made, but give accurate information as to the type and number of calculi present. Defective concentration of the dye and poor definition of the outline of the gall-bladder indicate cholecystitis. We have found, however, in a few cases in which the clinical history has pointed to cholecystitis, that the gall-bladder shadow appeared to be practically normal, yet at operation a gall-bladder with opacity of its wall and with an enlarged cystic gland was found, and from both gall-bladder wall and from the gland we were able to cultivate a streptococcus. This simply means that, in the early stages of a chronic cholecystitis, the gall-bladder function is maintained at a sufficiently high level to allow of an almost normal concentration of the dye. Whilst the test is, therefore, of the utmost value, it is not infallible and must be used, as must all such tests, as one of many means of clinical investigation.

## TREATMENT OF GALL-BLADDER INFECTIONS.

In this, as in all other diseases, we must, before considering the question of surgical intervention, assess as accurately as may be the chances of a natural cure and those offered by more conservative forms of treatment. In regard to spontaneous recovery from cholecystitis it is impossible to obtain accurate data. We are here dealing with a very chronic low-grade infection, the tendency of which is undoubtedly to persist and occasionally to flare up. The very long histories given by so many patients coming to operation indicate that, once established, the disease tends to be slowly progressive, and that in the diseased organ, crippled by fibrosis, gall-stone formation is more than likely. We know, further, that once stones have formed the chance of spontaneous cure has gone. Only the smallest gall-stones can pass down the ducts. Biliary colic, formerly thought to be due to the passage of a

stone, we now know to be due, in the vast majority of cases, to the temporary impaction of a stone in the neck of the gall-bladder. The almost total lack of a muscular coat in the bile ducts is sufficient evidence that colic is not due to spasm of the ducts.

Can we, then, by treatment influence the gall-bladder infection or prevent the formation of stones? A primary source of infection in the teeth or tonsils should be searched for, and, if found, dealt with. There is now a certain amount of reliable evidence that where there is infection of the bile passages by *B. coli* the administration of very large doses of hexamine will influence the course of the infection in a favourable manner. In several cases of chronic cholangitis I have seen undoubtedly, if temporary, benefit follow the administration of this drug. In the majority of cases of cholecystitis, however, we are not concerned with a catarrhal *B. coli* infection of the passages, but with an intramural streptococcal infection of the gall-bladder, and I know of no drug which will influence this. The use of suitable stock streptococcal vaccines may prove to be of value, and this would certainly appear to be the most rational line of medical treatment.

To prevent the formation of gall-stones any measure which favours emptying of the gall-bladder and diminishes stasis should be of help. Regular muscular exercise, which has been neglected by so many of the patients suffering from this disease, must be insisted on. Fat must not be excluded from the diet, as we now know that it is the one substance which without doubt causes the gall-bladder to contract; hence the discomfort following its ingestion in patients who already have gall-stones. Large quantities of bland fluid should be taken, finishing at night with a tumbler of hot water with some baking soda. Every morning a small dose of magnesium sulphate or sodium phosphate is taken to promote a flow of bile.

It is doubtful, as McNec has shown, whether we can influence the cholesterol content of the blood or bile by avoidance of articles of diet rich in this substance—such as egg-yolk, sweetbread, etc. We err, however, on the right side in excluding them. Ox-bile, sodium oleate, and sodium salicylate, given separately or together, as in the popular preparation felamine, may, by promoting a flow of bile, help to diminish stasis.

We are, however, faced with the problem that, when once firmly established, infection of the gall-bladder is highly resistant to cure by other than surgical means. If, therefore, symptoms persist or recur in spite of the measures recommended above, operation should be undertaken before secondary changes in other organs or acute complications supervene.

*Operative Treatment.*

I do not propose to discuss any technical points in regard to operation, but merely to review the principles which should guide such treatment and the results which may be expected. In the first place, it is obvious that, as the disease is almost invariably intramural, removal of the gall-bladder rather than drainage is the rational treatment. Only where the general condition of the patient or local technical difficulties make the operation of cholecystectomy one fraught with a sensibly greater risk should cholecystostomy be performed. In my experience the removal of a diseased gall-bladder is not followed by any untoward symptoms. On the other hand, simple drainage of the gall-bladder, whilst giving temporary relief, is very frequently followed by recurrence of symptoms, and sometimes by recurrence of gall-stones; hence the impression in some minds that gall-bladder operations are not followed by permanent relief. Free exposure that will allow of adequate investigation of the ducts is a *sine qua non*, as the failure to recognize a floating stone in the common bile duct is one of the most fertile causes of recurrence of symptoms after operation. The stomach and duodenum must be examined to exclude coincident ulcer, as, if present, this can usually be dealt with at the same time.

## SOME LESSONS FROM 452 BILIARY OPERATIONS.

During the past seven years I have operated on 452 cases of disease of the biliary passages. On reviewing these cases certain significant and interesting points are brought out. First in importance, perhaps, is the fact

that in 15 cases malignant disease of the gall-bladder was found. The average age of the patients in this group was 64, and in all a long-standing history of gall-bladder disease was given. In every case gall-stones were present and there was evidence of old-standing cholecystitis. In only one of these cases was the disease removable, and in that one fatal recurrence took place two years later. The risk of malignant disease is therefore no small one, and is a strong point in favour of timely operation.

In 6 cases the operation was carried out for acute haemorrhagic or gangrenous pancreatitis. In 5 of these cases, which were all fatal, a long-standing history of cholecystitis and gall-stones was given. The average age of the patients in this group was 60 years. In 3 cases (jaundiced patients) an irremovable carcinoma of the common bile duct was found, and in 7 a carcinoma of the head of the pancreas. In all of these 10 cases a palliative cholecyst-enterostomy was performed. Excluding these 31 cases (25 malignant and 6 acute pancreatitis) there remain 421 cases, of which 357 were cases of cholecystitis, with or without cholelithiasis. The sex ratio was 91 males and 306 females, and the average age at operation was 50 years. The disease was found with equal frequency in hospital and private practice (213 hospital, 184 private cases).

Several striking differences were noted in the two social classes, however. In the first place, there was a much larger percentage of male cases in private practice—30 per cent. to 17.3 in hospital practice—due, no doubt, to the sedentary occupation in the former. Secondly, the average age at operation in private cases was 54, in hospital cases 46.5, and the length of history corresponded to this age difference—that is, expectant and medical treatment was persisted with much longer in those in better financial circumstances. The most notable difference, however, was in the operative mortality, which in private cases was 6 per cent. and in hospital cases 1.4 per cent. This pronounced difference was attributable to the secondary changes and complications which had developed in many of the former; thus in the fatal group there were examples of subacute pancreatitis, 2 cases; cholecystitis with cirrhosis of liver, 2 cases; bleeding duodenal or gastric ulcer, 2 cases. Furthermore, the incidence of carcinoma of the gall-bladder in private was exactly double that in hospital practice, and as in many of these cases the patient survived the operation for only a few weeks or months the penalty of delay becomes the more evident.

It must be clearly understood that it is the age and severity of the disease, and not the age of the patient, which is the important factor in prognosis as regards operation. In my experience elderly patients stand operation on the biliary passages very well, provided none of the more dangerous complications have arisen. Thus among the 74 patients in this series who were over 60 years of age at operation only 5 died (6.7 per cent.), and among the 15 patients over 70 years of age there was but one death.

In dealing with elderly or bronchitic patients the advantages of local anaesthesia, aided by twilight sleep, cannot be too strongly emphasized. On numerous occasions I have removed the gall-bladder and stones from the common duct under such anaesthesia without the patient being conscious of the operation.

A large proportion of patients suffering from gall-bladder disease are grossly obese, and their muscles, including heart muscle, are flabby and in poor condition. It is a wise plan, and one which we practise regularly, to put these patients on a preliminary course of exercises for three months, that they may get into training for the operative ordeal. The remarkable improvement in general tone with loss of weight which results makes the operation both easier and safer.

Cholecystectomy was performed in 253 cases, cholecystostomy in 144. In the earlier years of the period under review cholecystostomy was the commoner operation, but in the past three years it has been almost entirely replaced by cholecystectomy, with no increase in operative mortality and a vast improvement as regards the diminution of post-operative morbidity.

In 257 cases calculi were present in the gall-bladder, in 140 cases cholecystitis without stone. The improvement in health following cholecystectomy in the 76 cases of the

latter group in which this operation was performed was, almost without exception, gratifying; in the 64 cases in which drainage of the gall-bladder was practised the improvement following the operation was, in many cases, only temporary.

#### Common Duct Stones.

In 47 cases—that is, 18 per cent. of the cases of cholelithiasis—one or more stones were found and were removed from the common duct. In the majority of patients in this group the history of recurring jaundice with colic, rigors, and loss of weight left no doubt as to the presence of a stone in the duct. In a third of the patients in this group, however, the history did not present anything approaching the typical Charcot syndrome, the stones being of the silent, floating type. Without adequate exposure and careful exploration they might readily have been missed, and indeed in 9 cases a previous operation for gall-stones had been performed.

When the patient, at the time of operation, was not deeply jaundiced the gall-bladder was removed. When the patient was jaundiced, or otherwise very ill, it was drained. There were three deaths in this group—a mortality of just over 6 per cent. The improvement in health, and rapid gain in weight, following a successful operation for stone in the common duct are remarkable.

#### CONCLUSIONS.

Infection of the gall-bladder is probably the commonest of all abdominal maladies, particularly among persons of sedentary habits.

It is usually an intramural blood-borne streptococcal infection, and is frequently associated with the formation of gall-stones.

If neglected serious, and often fatal, complications may ensue.

When firmly established the disease can only be cured by radical surgery.

In the absence of secondary changes and complications, such as malignant disease, pancreatitis, hepatic cirrhosis, and insufficiency or toxic myocarditis, operation has a low mortality and the results, as regards subsequent health, are very good.

Elderly patients may be safely operated on under twilight sleep and local anaesthesia.

I wish to express my thanks to Mr. J. J. M. Shaw for the specimen depicted in Fig. 5; to Mr. C. F. W. Illingworth for his help in the investigation of the cases of cholesterosis, and to Dr. A. L. Wilkie, whose remarkable work forms the basis of our present attitude towards cholecystitis.

## THE X-RAY DIAGNOSIS OF PATHOLOGICAL CONDITIONS OF THE GALL-BLADDER.

BY

JAMES F. BRAILSFORD, M.B.BIRM., M.R.C.S. ENO.,  
RADIOLOGIST, ST. CHAD'S HOSPITAL, BIRMINGHAM.

(With Special Plate.)

FIVE years ago the generally accepted opinion of physicians and surgeons was that a report on the x-ray examination of the gall-bladder was of no value. This was due to the fact that though Beck (1899) had demonstrated the shadows of gall-stones on radiographs, most radiologists were of the opinion that it was a rare and chance finding.

Thurstan Holland and Robert Knox in this country, Pfahler, Case, Cole, George, and Leonard in America, and Haenisch in Germany, who carefully studied the problem, came to the conclusion that gall-stones could be demonstrated in a fairly large percentage of cases, and that the percentage of correct x-ray diagnoses of gall-stones grows in proportion to the intensity of the interest, the more careful attention, the refinement of the technique, the study of the establishment of a diagnosis, the training of the eyes, and the improvement which comes of constant use and experience. (An account of the earlier work on gall-bladder radiography was given in a previous paper.)

The number of radiologists who hold this opinion is steadily growing. My own experience is that about 30 per

cent. of gall-stones contain sufficient calcium to cast a shadow which can be recognized on a good average radiograph. A small proportion of these are very opaque, and cast shadows as dense and as typical as the densest renal stone. These are usually ring-shaped or typical faceted gall-stones, the aggregation of which gives the outline of the gall-bladder (see Fig. 1). The majority, however, are ill-defined flaky shadows which can only be seen on good quality radiographs taken so rapidly that peristaltic and body movements are eliminated, as the slightest movement completely obliterates the shadows.

With the added development and improvement of Graham's cholecystography the x-ray diagnosis of pathological conditions of the gall-bladder ranks as high for a diagnostic procedure as the barium meal does for the examination of the stomach and duodenum. I have carried out nearly 500 x-ray investigations on the gall-bladder, and the high percentage of accurate results, as proved by operation, in my opinion fully justifies the procedure. Most of the patients were sent because of obscure symptoms in the upper abdomen, which were not sufficiently characteristic or acute to warrant the surgeon doing a laparotomy. Some were sent to confirm the clinical diagnosis of gall-stones. The value of the test for such conditions will be seen from the short histories which are given at the end of this paper.

I have continued to use the intravenous method of administration of the dye—except in a few instances where I have not thought it advisable, or where difficulty has been met with in injecting the vein—because I regard it as the most accurate. This method has been used to confirm the diagnosis of cholecystitis—indicated by non-filling of the gall-bladder when the dye has been given by the mouth—in five cases, and in each case a normal shadow of the gall-bladder was obtained.

It is essential that the technique of the intravenous injection be carefully carried out, and for this purpose it may be necessary to ask a surgeon to give the injection. This was my early practice, but for the last year or so I have been asked to carry out the injection myself, and from the occasional difficulties met with, and the fact that the test is in a sense quantitative, I am confident that the knowledge of these conditions enables the radiologist to give a more accurate report.

In a previous paper I have given the details of the technique, the errors which may be made owing to faults in the technique, the causes of failure, the nature of the reactions to the dye, the other methods of administration, and an estimate of the value of the test. In this paper I also pointed out the importance of (a) a preliminary x-ray examination, and (b) a subsequent barium meal while the gall-bladder is still visible. The preliminary radiography will often throw much light on the diagnosis, and may give indications which render the dye injection unnecessary.

Among the lesions previously unsuspected which have been revealed by the preliminary investigation are:

- (a) In the thorax: (1) Early phthisis with gastric symptoms. (2) Pulmonary tumour; primary or multiple secondaries from abdominal organs; hydatid cysts. (3) Aneurysm.
- (b) In the abdomen: (1) Stone in the kidney or ureter. (2) Calcified tumour in the kidney. (3) Gall-stones. (4) Lesions of the spine causing abdominal pain (tubercle, gumma, neoplasm, Paget's disease). (5) Abdominal aneurysm.

An example of the value of the preliminary examination was recently met with. A patient who had pain in the upper abdomen was cholecystographed by the oral method and the gall-bladder had failed to fill. Several months later he was brought for a confirmatory x-ray examination. The preliminary radiograph showed carcinomatous destruction of the body of the second lumbar vertebra.

The preliminary radiograph may show the gall-bladder full of opaque sand, which produces a shadow not unlike a normal gall-bladder filled with dye.

The details of the following case indicate that where the preliminary radiograph shows gall-stones it is advisable, particularly in these cases where the symptoms are atypical

of gall-bladder pathology, to carry out a barium meal investigation of the alimentary tract.

A married woman, aged 60, complained of indefinite pain in the upper abdomen. She gave a history of having had indigestion and a similar pain for several years, but during the last few months the symptoms had been more marked. The surgeon who was called in expressed the opinion that the symptoms were due to gall-stones, and arrangements were made for the removal of the gall-bladder. It had previously been decided to have an x-ray investigation, and this was proceeded with the day before operation.

The preliminary radiograph showed a collection of large gall-stones in the gall-bladder. A barium meal was given, and at the eighth hour an irregularity of the first part of the descending colon was seen (see Fig. 3). This irregularity was still present at the twelfth hour. Its appearance was so suggestive of a small carcinoma that I asked the surgeon if he would examine the area after he had removed the gall-bladder. This he did, and he found a carcinoma, which he resected. The patient made a good recovery.

Similarly it is advisable to follow up the cholecystography with a barium meal even in those cases where the symptoms strongly suggest a pathological condition of the gall-bladder and the radiographs show a normal gall-bladder filling (see Fig. 5), for in one case in my series in which the gall-bladder filled normally it was decided that operative measures were not indicated. No barium meal investigation was made. The patient went home and returned a fortnight later with a perforated duodenal ulcer from which she died. The *post-mortem* examination revealed the ulcer with massive adhesions and a normal gall-bladder.

On the other hand, two women patients, aged respectively 32 and 38, had complained of symptoms in the upper abdomen for several years, during which time they had been seen by several consultants, who had advised barium meal examinations; these failed to demonstrate any lesion. Their symptoms were attributed to neurasthenia until a cholecystographic examination showed that neither gall-bladder filled. In both cases at operation gall-stones were found in the gall-bladder and cystic duct.

All gall-stones shown on preliminary radiographs contain calcium, and it is considered that these are usually associated with inflammation; their demonstration is therefore of great diagnostic value. In no case where gall-stones were shown has the patient been entirely free from abdominal pain or discomfort.

One patient sent to me for an x-ray examination of the urinary tract, the left kidney being large and tender, gave no definite history of gall-stone colic, though the radiographs showed the gall-bladder to be full of stones containing calcium. She was not operated upon because a large calculus occupied the pelvis and calyces of the right kidney, in addition to a stone in the pelvis of the enlarged and inflamed left kidney (Fig. 1). A few weeks afterwards she had an acute attack of gall-stone colic, and these attacks were repeated so frequently during the next nine months that the patient was kept in bed. When they had ceased her condition improved. By the end of the year she was able to do her housework. A further x-ray examination (Fig. 2) at this time showed that though the kidney stones appeared identical with the previous radiographs only one small stone remained in the gall-bladder. A radiograph twelve months after this showed no gall-stones. She had put on 3 or 4 st. in weight, had no pain, and felt well.

In another case in which calcium gall-stones were shown on preliminary radiography, a radiograph taken some months afterwards showed no gall-stones; the gall-bladder failed to fill with the dye, and at operation only a little grit was found in the chronically inflamed gall-bladder, the gall-stones having been passed.

The details of the following case also demonstrate that the signs and symptoms may be atypical.

The patient, who had had her right breast removed for carcinoma a few years previously, had an attack of agonizing pain in the left hypochondrium. The pain radiated through the left side of the thorax and down the left arm, and lasted with great severity for twenty-four hours. The surgeon who had removed the breast was called in, but he could find no evidence of secondary growth, and suggested that the pain was due to hæmorrhage into a deep-seated secondary growth pressing upon nerves supplying the area. A radiograph was taken to demonstrate if possible the position and extent of the secondary deposits. The lung fields were seen to be clear, and the heart and aorta were normal in size, shape, and position. The diaphragm moved normally on both sides. I suggested that the pain might be due to gall-stones, as I had recently seen several such cases of gall-stone colic in which all the symptoms had been on the left side. A radiograph showed the gall-bladder to be full of gall-stones containing calcium, and isolated stones were shown in a line, suggesting that they were in the cystic duct (see Fig. 4).

Cholecystography had a setback in its early days owing to a proportion of the patients showing a reaction to the injected dye. This was chiefly due to the use of sodium tetrabromphenolphthalein, many preparations of which were impure and very toxic, while a solution of some preparations gave no denser shadow than water. Since Whitacre and Milliken showed that sodium tetraiodophenolphthalein could be used in smaller quantities, that it cast a better shadow, and the chemists have manufactured purer preparations of the dye, few toxic effects have been seen. They have not been entirely eradicated. Using this dye I have only seen five severe reactions—two in private practice and three in hospital. For nearly two years I saw no reaction, but recently a patient within fifteen minutes of the injection showed all the signs of severe shock.

This patient, a woman of about 30 years of age, gave a history of eight former operations, after several of which thrombosis had occurred in her legs. She now complained of pain in the gall-bladder area; she had been seen by several surgeons, who had diagnosed gall-stones, and advised that the gall-bladder should be removed. Owing to her previous experiences she did not wish to have an operation until more definite proof of the lesion had been obtained. She was acquainted with the details of a cholecystographic examination, but had been advised not to have it done. She, however, insisted on the test being done. The dye was injected at 11 p.m., and after fifteen minutes the patient developed all the signs of severe shock, which gradually passed off during the next hour. The next morning radiographs

were taken; they showed a gall-bladder shadow normal in size, shape, and density, and after taking food it gradually diminished in size. The patient said that she felt no effects whatever of the shock, and that the experience was not to be compared with the feeling after an anaesthetic.

It may be urged that it is preferable to do a laparotomy than risk a chance of a reaction, but the x-ray investigation in many cases proved that the laparotomy would have been useless. Further, the x-ray examination enables us to give a fairly accurate opinion of the function of the gall-bladder, and a laparotomy may fail to do this. It is also probable that the patient who reacts to the dye would be a very unfavourable subject for a general anaesthetic and a laparotomy, and so far it has been my experience that those patients who react have a gall-bladder which fills in a normal manner.

It will be seen, therefore, that while there are many patients with symptoms so severe and urgent that a laparotomy is essential, there are patients with symptoms so indefinite and atypical that no surgeon would care to do a laparotomy. In this latter type of case an x-ray investigation of the gall-bladder will often prove of much value.

## THE LATE RESULTS OF OPERATION FOR RENAL CALCULUS.

BY

J. F. DOBSON, M.S.LOND., F.R.C.S.,

PROFESSOR OF SURGERY IN THE UNIVERSITY, AND SENIOR SURGEON TO THE GENERAL INFIRMARY AT LEEDS.

(With Special Plate.)

An attempt has been made during the last two years to trace the late history of all the cases of renal and ureteral calculus upon which I have operated since the war. The cases investigated number about a hundred, and a very large proportion have replied to inquiries. It would perhaps be useful first to give the results and then to discuss certain points of interest which arise.

Recurrence and fatal anuria four years later	...	...	...	...	1

In one of the cases of pyelo-lithotomy there was a considerable degree of hydronephrosis, yet four years afterwards the patient is perfectly well.

The three unsatisfactory cases after nephro-lithotomy are the following.

*Case 1.*—In June, 1920, right nephro-lithotomy was performed on a man for a single calculus in the kidney. There was a small stone in the corresponding ureter, which, however, was passed just before the operation. He recovered satisfactorily and remained free from symptoms for a time. Some two years later a recurrence of calculus was found in both kidneys, and the patient died from acute haemorrhagic pancreatitis five years after the original operation.

*Case 2.*—In 1920 nephro-lithotomy was performed on a woman aged 48; one stone was removed from the right kidney. Six years later she reported that she had had one or two attacks of haematuria since her operation, and x-ray examination revealed a single calculus in the pelvis of the left kidney and two or three calculi in the right kidney. Owing to the unsatisfactory condition of the patient further operative treatment was not thought advisable.

*Case 3.*—A woman, aged 28, was operated upon in 1925. Three stones were removed from the right kidney, one by an incision into the pelvis and two through an incision through the lower calyx, which contained purulent urine. She was readmitted a year later with a discharging sinus. X-ray examination was negative. The kidney was explored and found to be so densely adherent to the surrounding structures that nephrostomy only was done. The patient's general condition improved very much, and a subcapsular nephrectomy has now been successfully performed. In this case primary nephrectomy would have been preferable to a conservative operation.

The following three cases are remarkable.

*Case 4.*—In a woman who was operated upon in 1921 the left kidney contained multiple calculi; its function was very deficient. The kidney was explored and found to be hydronephrotic. There was a large quantity of putty-like material in the pelvis in addition to several calculi. It was thought desirable to perform nephrectomy, but the patient's husband, a doctor, demurred. The patient made a good recovery; she had some pain and frequency for a time, but this disappeared after a course of vaccine treatment. Five years later she was perfectly well. There is, however, no information as to the functional capacity of the kidney that was operated on.

*Case 5.*—A man, admitted in 1919, had suffered for some months from attacks of typical renal colic on the left side. The pain commenced in the loin and radiated downwards into the testicle and the thigh. Slight haematuria always accompanied the attacks of colic. X-ray examination showed the renal areas to be free from calculus and demonstrated a shadow in the pelvis on the left side, but not in the normal course of the ureter. An opaque ureteral catheter was passed up the left ureter and was arrested; an x-ray photograph showed the catheter in contact with the shadow, which was therefore thought to be a calculus impacted in an abnormally placed ureter. Unfortunately a pyelogram was not taken. Extra-peritoneal exploration of the ureter was performed, and the left kidney was found just below the pelvic brim with a calculus in the pelvis. Nephro-lithotomy was performed. Seven years later the patient was perfectly well.

*Case 6.*—A man, aged 33, was admitted in 1924 with the usual symptoms of a calculus in the left kidney. A skiagram showed the shadow of a calculus, and no suspicion was entertained that it was in any way unusual. Cystoscopy showed adequate function of both kidneys. Exposure was difficult, and the organ was found to be a

horseshoe kidney with the ureter in front and running downwards over the isthmus. The stone was in the pelvis and was extracted by an incision on the anterior surface. Two years later the patient was perfectly well and had gained 23 lb.

*Case 7.*—In one instance a stout woman developed a fistula after uretero-lithotomy; a small stone was impacted in the ureter just above its entrance into the bladder wall. The kidney was not functioning, and a catheter was arrested by this stone. The ureter was exposed and found to be very little dilated. An incision was made at the level of the pelvic brim and efforts were made to extract the calculus, without avail. The bladder was displaced, the uterine artery tied, and the stone extracted through a direct incision; it was tightly gripped by the ureter. The wound healed, but three weeks later a fistula formed. A dilated and infected kidney was removed. The patient is now well.

#### Recurrence.

The after-history of seven cases was investigated where the clinical symptoms were very suggestive of calculus, but in which x-ray examination was negative. Six of these cases have had no further trouble, one has had one attack of colic since.

In the series of cases investigated a certain number are known definitely to have had recurrence of calculus.

	Recurrences.
After pyelo-lithotomy ... ..	0
" nephro-lithotomy ... ..	2
" uretero-lithotomy ... ..	0
" nephrectomy ... ..	0
For bilateral calculus ... ..	1
After nephrostomy ... ..	0
	3

Other cases presented symptoms which might possibly be due to recurrence of calculus.

	Possible Recurrences.
After pyelo-lithotomy ... ..	2
" nephro-lithotomy ... ..	0
" uretero-lithotomy ... ..	2
" nephrectomy ... ..	3
For bilateral calculus ... ..	1
After nephrostomy ... ..	3
	11

Two of these cases have been x-rayed with negative results.

We have here definite and certain evidence that recurrence occurred in 3 cases, and we have in other 11 cases symptoms developing later on which might possibly be due to recurrence. Unfortunately it has not been possible to investigate all these cases, but I have recently seen a woman of 56, upon whom I operated fourteen years ago for bilateral renal calculus; she has been well until recently, but now has recurrence in both kidneys. Further, in some of the cases operations had been performed previously for calculi. In two of the nephrectomy cases stones had been removed from the kidney by other surgeons many years previously. In one of the cases of nephro-lithotomy a stone had been removed ten years previously by another surgeon. One case of renal calculus occurred in a patient for whom suprapubic lithotomy was done ten years previously.

According to Braasch and Foulds evidence of recurrence of calculus is found in 10 per cent. of cases after operation, the incidence of recurrence being higher after nephro-lithotomy than after pyelo-lithotomy. Undoubtedly some "recurrences" are due to small stones remaining undetected at the first operation.

According to Rovsing recurrence is due to infection with urea-decomposing organisms. Urinary fistula following operation even of short duration is the common cause of this infection. He states that pyelo-lithotomy, since it frequently causes a fistula, is contraindicated, and nephro-lithotomy without drainage should be performed instead. It is evident that recurrence of calculus is a very serious danger, and stones left behind at operation are no doubt in part responsible. This risk will be largely eliminated by radiography of the kidney during operation.

Rovsing's views on the risk of a staphylococcal infection from a temporary urinary fistula are no doubt correct, though I imagine few surgeons would agree that even a temporary leak is at all common after pyelo-lithotomy. Rather is it thought that recurrence is more likely after nephro-lithotomy than after pyelo-lithotomy. The latter operation is usually done for single, comparatively small stones, with a kidney little damaged and not seriously

infected. The former operation is performed in cases of multiple or large calculi, with some or even a considerable hydronephrosis, or with an infection of more or less severity. The risk of recurrence being less after pyelo-lithotomy than after nephro-lithotomy indicates clearly the advantage of removing a calculus before it has had time to produce those changes in the kidney which favour recurrence.

In addition to the risk of recurrence of calculus in the kidney there are other changes which sometimes occur at a late stage after conservative operations for calculus. In this series of cases nephrectomy for pyonephrosis (with no recurrence of calculus) was performed in two cases—in one four years after removal of a stone from the ureter, and in the other eighteen years after a nephro-lithotomy; in another case nephrostomy was performed for a pyonephrosis one year after nephro-lithotomy.

The figures above quoted show clearly that although the results of operations for renal calculi are on the whole exceedingly good, the risk of recurrence is such that every effort ought to be made when the opportunity is present to adopt such measures as may be possible to avoid this unsatisfactory sequel. In this connexion we must consider first the diagnosis of calculi, and secondly, the methods practised for their removal.

#### DIAGNOSIS OF RENAL CALCULUS.

The diagnosis of renal calculus rests very largely on the results of the x-ray examination.

#### Cases with Typical History, Colic, Haematuria, etc.

In the majority of cases the results of x-ray examination are conclusive as to the presence or absence of calculus, though sometimes a negative finding is inaccurate. It has happened to me on one or two occasions to see a calculus in the bladder which had not been recognized by the radiologist; it is reasonable to assume that a similar stone in the kidney might escape detection. It has also happened that when an x-ray examination has been negative patients have subsequently passed a calculus. On a few occasions when the symptoms were very suggestive and the x-ray examination negative I have taken a pyelogram and have repeated the x-ray examination on the following day, hoping that some of the sodium bromide would have been absorbed by a calculus, which would then throw a shadow. I have not as yet had such a case. In such cases resort should be had to pyelography; a lighter area may indicate the presence of a stone, and in any case it will probably demonstrate the cause of the patient's pain—such as a small hydronephrosis or a kinked ureter, etc.

#### Cases with Atypical Symptoms.

There are a number of patients with renal calculus who suffer very little pain, merely a vague aching in the back, without such obvious changes in the urine as to drive them to seek advice. An x-ray examination of the urinary tract should not be omitted as part of the routine investigation of cases of indefinite backache, particularly if there are any changes in the urine. In some cases the calculi are absolutely latent, and may only be detected accidentally. There are cases of haematuria where pain is negligible. A complete x-ray investigation of the whole urinary tract is an essential step in the examination of a case of haematuria. Similarly I have seen cases of calculous pyonephrosis with large quantities of pus in the urine where the history of pain is of the vaguest.

#### The Interpretation of the X-ray Photograph.

In this matter the practice of different surgeons varies; some prefer their own interpretation, some attach more importance to the opinion of the radiologist. My own practice is to accept the view of the radiologist, though I see all films myself and form my own opinion, usually before seeing his report. Consultation between the two persons concerned is necessary in any case of doubt. As to pyelograms I prefer my own interpretation. It is necessary to remember that the x-ray examination is only a part, though a most important part, of the complete investigation of a case of suspected renal calculus.

Occasionally mistakes may be made as to the number of stones in the kidney. Sometimes two overlapping stones are regarded as one, or two partially overlapping stones as one large stone. On one occasion the x-ray film indicated the presence of two calculi in the pelvis of the kidney, and at the operation only one calculus was found; only after considerable search was it discovered that the second shadow was due to a deposit in the twelfth rib, which had been removed to facilitate the exposure of the kidney. The shadow was demonstrated by x-raying the portion of rib removed.

There can be no doubt of the value of profile radiography in the diagnosis of renal calculus, and it should be done as a routine.

#### *X-ray Photography during Operations on the Kidney.*

This method of ensuring the removal of all fragments of calculi in the kidney I have used only in two cases, but they were both very instructive, and with a better apparatus (the one used was a makeshift) and more experience of the method it will undoubtedly be of great value. We did not attempt to screen the exposed kidney, but took two or three films as soon as the kidney was exposed. In an ordinary light operating theatre it must be a matter of extreme difficulty to accommodate the eyesight sufficiently to obtain a satisfactory view with the screen. The main difficulty was in withdrawing the kidney sufficiently to obtain a film which did not show the edges of the wound. However, as this merely interferes with the shadow of the kidney pelvis, it is not so very important. The calculi which are most likely to be overlooked are small bodies in the calyces and the substance of the kidney. A valuable feature of this method is that it will enable us to say that indefinite shadows in the kidney area, associated with a definite calculus and themselves simulating calculi, are extra-renal.

In the first case x-ray examination previous to operation showed a calculus in the pelvis of the right kidney and a small shadow in the kidney area. The right kidney was exposed and an x-ray photograph was taken; this showed the stone present in the pelvis, with some other small shadows also in the pelvis, but none in the substance of the kidney. The pelvis was incised, and a large stone and two or three small gritty fragments were removed.

In the second case x-ray examination showed a calculus in the right kidney with some small additional shadows in the kidney area. The kidney was exposed and a stone felt in the pelvis, the skiagram of the exposed kidney showing no calculus in the kidney substance. Pyelolithotomy was performed.

There may on occasions be considerable difficulty in distinguishing between the shadow of an enlarged gland and that of a renal or ureteral stone. The following case is an example.

**Case 8.**—A woman was admitted to hospital in 1925 complaining of renal pain. The urine contained a little albumin and a few pus cells. The x-ray photograph showed a shadow which was thought to be a calculus impacted in the upper part of the ureter (Fig. 1). A pyelogram (Fig. 2) was taken; this showed a little hydronephrosis with some dilatation of the ureter down to the level of the shadow, which was clear of the ureter. Exploration revealed a calcareous gland with adhesions and fibrous thickening obstructing the ureter. The patient was completely relieved of her symptoms by freeing the ureter.

In cases such as this profile radiography with the opaque catheter in position, and perhaps a pyelogram, will be a great help in diagnosis.

#### DIAGNOSIS OF CHANGES IN KIDNEY AND URETER CAUSED BY THE PRESENCE OF CALCULUS.

It is not sufficient merely to recognize the presence and the number of calculi; the extent to which the function of the kidney has been disturbed and the presence of secondary destructive changes must also be ascertained.

It may be obvious that a pyonephrosis has developed; the presence of a tumour, a large quantity of pus in the urine, the absence of indigo-carmin from the affected kidney on cystoscopy, together with general symptoms, make the diagnosis sufficiently obvious. It then only remains to ascertain the presence of the second kidney, to prove its functional capacity, and, considering all the

clinical features of the case, to determine whether nephrectomy, a nephrostomy, or nephrostomy with secondary nephrectomy is indicated.

Advanced renal changes may, however, be present in the absence of a palpable kidney. In many cases where a calculus in the pelvis or ureter has been in position for some time some degree of hydronephrosis is present. It is important not only to ascertain the extent to which the kidney tissue has atrophied, but also to form some estimation of the degree of infection present.

Confining ourselves for the present to the consideration of cases of unilateral calculus, and to cases where radiography shows a shadow in the kidney area and no suggestion of a calculus in the ureter, we wish to determine by cystoscopic methods the presence or absence of a hydronephrosis, and to ascertain as far as possible the extent of the infection which has occurred.

Hydronephrosis can be recognized by pyelography. Is it desirable to take a pyelogram in every case of renal calculus? In practice it is not possible, but in a tolerant patient it should be done. The advantage of a preliminary pyelography is that it may enable the surgeon to determine before operating whether a nephrectomy is likely to be necessary. The alternative is to decide this point when the kidney is exposed, it having been previously ascertained that the second kidney is efficient.

#### *Determination of the Functional Capacity of the Affected Kidney.*

This may be done by relying on the evidence obtained after an injection of indigo-carmin. In some cases this may be sufficient. A more scientifically satisfactory method is to catheterize the ureter, take the phenolsulphonephthalein proof, and collect a specimen of urine from the affected side for chemical and bacteriological examination.

The presence and capacity of the second kidney can be ascertained by cystoscopy after an injection of indigo-carmin. With an adequate excretion of the dye, and in normal time, the presence of the second kidney may be accepted. The more completely satisfactory proceeding is to catheterize the ureter, take the phenolsulphonephthalein proof, have a chemical and bacteriological examination of the urine, and perhaps take a pyelogram.

I would not urge that these investigations should be a routine proceeding. There is no doubt that some patients become very restive under repeated and uncomfortable investigations, and sometimes a necessary operation is declined. The surgeon should not allow his urological curiosity to outweigh the dictates of common sense. On the other hand, the man who would explore a kidney for calculus without previously ascertaining, not merely the presence, but something of the functional capacity of the second kidney, is exposing his patient to very unnecessary risks.

Let us assume that we have determined the presence of a calculus in the pelvis of the kidney, with some degree of hydronephrosis and some impairment of kidney function. We ought to ascertain, if possible, the presence and degree of infection of that kidney. It is very desirable to do this, as with a considerable degree of hydronephrosis and a definite infection recurrence of calculus formation is rather probable, and a primary nephrectomy may be preferable to a conservative operation. It is not easy to determine this; the amount of pus, the profusion of growth of organisms, and the extent of impairment of renal function are to be taken into account. In some cases the desirability or otherwise of nephrectomy can only be determined on the operating table. It must be remembered that a kidney which is functioning badly may recover considerably after the stone is removed.

#### URETERAL CALCULUS.

Not infrequently radiography shows a doubtful shadow. An opaque catheter passed up the ureter will almost always clear up the difficulty.

The presence of a calculus in the ureter having been recognized it remains to ascertain, if possible, the extent of the changes in the kidney. The ureter may be completely blocked; there may be no secretion on that side, and

the ureteral catheter is arrested by the stone. In such case one can carry investigation no further than to ascertain the facts about the second kidney. It is very desirable, however, to ascertain the presence or absence of dilatation of the ureter above the calculus, and in all cases an attempt should be made to take a uretero-pyelogram.

It is possible that with a calculus in the ureter there may also be an obvious pyonephrosis. This presents no difficulties in diagnosis. The problem is to ascertain in the less advanced case to what extent the kidney tissue has been distended or destroyed, and what are the prospects of recovery of the kidney after the ureteral obstruction is removed, or what are the chances of recurrence of calculus. The surgeon will not here have the advantage of exposing the kidney at the operation, at any rate in cases where the stone is in the pelvic ureter. In the absence of proof it is generally wise to extract the stone and await events. If recurrence takes place or pyuria is persistent a secondary nephrectomy may be done.

#### CHOICE OF OPERATION.

Whether surgeons are too ready to practise conservative operations and too unwilling to remove a doubtful kidney is arguable. The risk of recurrence being bilateral must always be borne in mind, and if there is a recurrence of calculi the patient is better off with two damaged kidneys containing stones than with a single such kidney. On the other hand, is an infected and somewhat dilated kidney, one likely to be the seat of a recurrence, a factor in inducing calculus formation in the second kidney?

#### Exposure of the Kidney.

The retroperitoneal route is the usual, and the choice of incision is immaterial. The surgeon need not fear to divide muscles, as hernia is extremely rare, and he should never hesitate to remove the last rib. The kidney should be drawn out and handled as gently as possible.

#### Pelvic-lithotomy.

A sufficiently large incision should be made in the pelvis, not encroaching on the ureter. The stone should be extracted with the utmost gentleness; large forceps should never be passed into the pelvis and the stone forcibly removed. By the use of small forceps and little levers even a considerable stone can be extracted without bruising the edges of the wound. The wound in the pelvis is sutured whenever possible, and that is practically always, and in addition the thickened fatty tissue is sutured in place as a reinforcement.

I have little experience of extended pelvic-lithotomy, where the incision in the pelvis is carried on into the substance of the kidney. It may involve ligation of a retroperitoneal artery, which might devitalize a considerable area of kidney tissue.

#### Nephro-lithotomy.

This is necessary usually in cases of large calculus or of multiple calculi. The incision in the kidney should be as small as possible, having due regard to the fact that the calculus or calculi must be removed intact and not in fragments, and the kidney tissue must not be lacerated. At one stage in his career my late chief, Mr. Harry Littlewood, was in the habit of splitting the kidney from end to end for the proper exposure and extraction of calculi, and he had surprisingly few after-haemorrhages; but the functional capacity of a kidney so treated must have been very seriously diminished.

The discovery and removal of small calculi in one of the calyces may be extremely difficult. In one case, where there was a calculus in the pelvis and another small shadow in the kidney area, after the first stone was removed by pyelotomy the second supposed calculus could not be detected even by incision of the kidney. A stream of fluid from the nozzle of a syringe passed through the kidney incision washed a small calculus into the pelvis, whence it was easily removed. Possibly it would be well in all cases to wash out the pelvis and calyces with a stream of sterile water under pressure to remove any tiny calculi which might be left behind.

During the course of a nephro-lithotomy one is occasionally called upon to decide whether it is really wise to attempt to preserve the kidney.

#### Nephrectomy.

Simple as it is in many cases, nephrectomy may be impossible with an adherent pyonephrosis. A sufficient exposure of the kidney, deliberation, and the greatest care in recognizing and separating the various important structures which are adherent—the inferior vena cava, the duodenum, the colon—are essential. I prefer to separate the pelvis and ureter from the vessels, to tie veins and arteries separately, and to divide the ureter at a low level as the last step. It is important not to tear the pelvis, and I never use a large clamp on the pedicle if it can possibly be avoided. One cause of a persistent sinus after nephrectomy is the inclusion of a portion of the pelvis in the pedicle, and this is favoured by the use of a clamp. An extracapsular nephrectomy is far preferable to a subcapsular, as in the latter case it is not easy to separate the vessels from the pelvis. In some cases, however, the subcapsular operation is the only possible method.

Nephrectomy is possible in the majority of cases of calculous pyonephrosis. There are, however, definite contraindications. Where pyuria has been present for years, and the patient is anaemic, feeble, and emaciated, a prolonged and difficult operation is attended with considerable risk.

In one case a large adherent pyonephrosis was removed intact with great difficulty; the patient made a very slow recovery, remaining feeble and anaemic for some months, ultimately, however, regaining her health. The tumour was not examined for some time after the operation, and it was then found that the suprarenal capsule, firmly adherent to and indistinguishable on the surface of the kidney, had also been removed.

I have not wounded the inferior vena cava in performing nephrectomy for a calculous pyonephrosis, but have done so twice in doing nephrectomy for other conditions. In both cases the vessel was controlled by forceps left in place, and recovery occurred without incident and without any subsequent ill effects.

#### Nephrostomy with Secondary Nephrectomy.

This is sometimes satisfactory, though in the majority of cases probably a primary nephrectomy would be preferable. Nephrostomy alone has its dangers, and a secondary nephrectomy, usually a subcapsular operation, may be extremely difficult.

#### Nephrostomy Alone.

On occasions this is the only proceeding which is permissible, usually because of the general condition of the patient. The kidney is explored and incised with as little disturbance of the perirenal fatty tissue as possible; the calculus or calculi are extracted, any septa which prevent drainage are broken down (it is not advisable to do this with the knife owing to the risk of haemorrhage), and provision is made for drainage and antiseptic instillation. I think the late results of these cases are better than is commonly thought.

The following are illustrations.

*Case 9.*—A lady, aged 67, had suffered for years from backache and pyuria; a large pyonephrosis had developed, with rapid deterioration of health. She was too ill to be removed even for an x-ray examination. The kidney was exposed, a large calculus measuring 3 in. by 4 in. was extracted, and the kidney drained. The wound healed completely in a very short time, and the patient lived for nine years in reasonable health and comfort.

*Case 10.*—Another case in which even less was done. A lady of 76, who suffered from rheumatism and had just undergone two operations for glaucoma, developed a large pyonephrosis. Under a local anaesthetic the kidney was incised and drained, no attempt being made to find a stone. She is now, a year later, in reasonably good health, with a slight pyo-urinary discharge which gives little trouble.

*Case 11.*—A woman, aged 53, was admitted with a pyonephrosis, which was drained. No calculus was detected at the time, but subsequent x-ray examination showed a small calculus in the lower part of the pelvis of the kidney. Nephrectomy was declined. The wound closed, but re-discharged two months later. She had no further trouble for eighteen months, when it discharged again for a period of sixteen months. Since then it has not

discharged, and so far as her kidney is concerned the patient is quite well (six years afterwards). She is, however, troubled with gall-stones.

*Case 12.*—A woman, aged 60, suffered from a calculus pyonephrosis with multiple calculi. Nephrostomy was performed and the calculi removed, practically no kidney tissue remaining. The wound healed very quickly, and the patient is now, three years later, in good health.

*Case 13.*—A woman, aged 34, had many calculi in a large pyonephrotic kidney. She was too ill for nephrectomy. The calculi were removed and nephrostomy done. A year later the patient was in good health and doing all her own housework. There was a slight watery discharge from the wound.

*Case 14.*—A woman, aged 58, with pyonephrosis and a large branching calculus, underwent nephrostomy with removal of the calculus. Four years later she was in moderate health and able to do some housework, but the wound was discharging.

*Case 15.*—A woman, aged 63, with large calculus pyonephrosis. The calculi were removed and nephrostomy performed. Nephrectomy was advised and refused. The patient improved and the wound healed. She was admitted two years later with a perinephric abscess which proved fatal.

It is evident that some patients may recover perfectly after a simple nephrostomy or may be left with a sinus which causes little trouble; but in all reasonably promising cases a secondary nephrectomy should be done.

#### *Extraction of Calculi in the Ureter by Cystoscopic Procedures.*

These methods have been practised extensively in America of late years, and varying reports are given. According to Peacock, ureteral dilatation was successful in inducing the passage of the calculus in 50 per cent. of cases so treated. Various procedures have been recommended—for example, passage of a ureteral catheter alone; dilatation of ureter by passing catheters of varying size or by dilating forceps; dilatation and injection of olive oil and other substances; enlargement of ureteral orifice (1) by diathermy, (2) by operating cystoscopic scissors, subsequent passage of catheter, and injection of oil.

My personal experience of these methods is comparatively limited. In one case in a woman a stone presenting at the orifice of the ureter was persuaded into the bladder by passing a Luys's cystoscope and by incising the lower end of the ureter on to the stone. In another the ureteral catheter withdrew the calculus. In another case the ureteral orifice was enlarged with the diathermy terminal and oil injected; this was followed by the passage of the calculus. In still another case mere dilatation and injection of oil sufficed.

There can be no doubt that these cystoscopic methods are of great value. Probably some of the stones which pass after such instrumentation would have passed in any case; but some would remain impacted, would increase in size, and induce destructive changes in the corresponding kidney.

I have no experience of division of the lower end of the ureter with the cystoscopic scissors. The objection to this would appear to be that haemorrhage would occur and obscure the field. Enlargement of the orifice by the diathermy terminal has not this disadvantage, but is not without its dangers. Marion<sup>1</sup> reports a case in which stenosis of the orifice occurred, the calculus was not passed, and the kidney, becoming pyonephrotic, had to be removed.

Recently I have had a case in which a small triangular calculus was impacted at the lower end of the left ureter, the pointed tip being visible through the cystoscope. Enlargement of the orifice by the diathermy terminal, dilatation, and injection of oil were unsuccessful, and transvesical uretero-lithotomy had to be performed.

On the whole, probably dilatation of the orifice with injection of oil will be as efficacious as any other procedure. In the case of small calculi this ought to be done before uretero-lithotomy is considered.

#### *Uretero-lithotomy.*

Various methods of approaching the pelvic portion of the ureter are practised. I prefer the extraperitoneal, outer border of the rectus incision (Battle). I have not usually found it necessary to tie the deep epigastric vessels. When the ureter is dilated it may be incised at any convenient point and a pair of forceps passed down; the stone is usually extracted without difficulty. But in cases where the ureter is not appreciably dilated removal is not so easy.

In some cases an attempt to extract a stone by forceps passed down the ureter from an incision at the level of the pelvic brim has failed, the ureter has had to be exposed at a lower level, perhaps after tying the uterine artery, and the stone extracted by a direct incision at the seat of impaction. In most instances this has been quite satisfactory, but in one case a fistula formed and a secondary nephrectomy became necessary.

By these methods it is almost always possible to extract a calculus from the ureter; but there are cases, where the stone is impacted close to the wall of the bladder, which are exceedingly difficult, and in some a combined ureterotomy and cystotomy has been done. In one such case after the bladder was opened a No. 1 urethral bougie was passed down through the preliminary incision in the ureter past the stone into the bladder. The tip was then seized and pulled downwards, the conical upper end of the bougie drawing down the stone to the orifice, when it was easily extracted by an incision in the bladder wall.

#### *Operation for Bilateral Renal Calculus.*

A number of cases of bilateral renal calculus have been seen and some have been operated upon. The most satisfactory cases are those in which there is a single calculus in the pelvis of each kidney, with little dilatation of the kidney and only a mild degree of infection. When the calculi are multiple it is always a question whether an operation is worth while. I have at the present moment four such cases under observation; two (both recurrences after previous operation, one of my own, one of another surgeon) could not possibly survive any further interference, and in the other two the symptoms are very slight and I am disinclined to interfere. The operations should be done at two sittings, and it is a question which kidney should be attacked first. I prefer to do the better-kidney first.

The two following cases are of interest, the first possessing a wandering calculus and the second being an example of recurrence.

*Case 16: Wandering Calculus.*—A woman, aged 33, was admitted with a history of right renal colic; no pain in left side. The first x-ray photograph taken (Fig. 3) showed a calculus in the pelvis of the left kidney and a shadow on the right side in the course of the ureter, the significance of which, however, was not realized at the time. The second radiograph (Fig. 4), however, showed a calculus in the pelvis of the right kidney in addition to the one on the left side. Further x-ray examination showed that the calculus was sometimes in the ureter and sometimes in the kidney. A pyelogram (Fig. 5) taken of the right side showed a considerable degree of dilatation both of the ureter and of the pelvis. Left pyelo-lithotomy was performed, and three weeks later the right kidney was exposed: the kidney was enlarged, the pelvis and ureter dilated. The calculus, found in the ureter, was pushed up into the pelvis and removed. A year later the patient was very well, but had slight pain and occasionally the urine was rather cloudy, with a sediment.

*Case 17: Recurrence.*—A woman of 50 with several calculi in both kidneys. Left nephro-lithotomy was performed, four stones being removed from the lower pole of the left kidney. Three months later right nephrectomy was done for a pyonephrosis containing five calculi. A year later the patient was readmitted with calculus anuria, and a small stone was removed from the ureter. The patient recovered, but died a year later at home from anuria. In this case perhaps palliative treatment would have been preferable.

#### *The Treatment of Renal or Ureteral Calculus Complicated by Other Lesions of the Urinary Tract Demanding Operation.*

Marion<sup>2</sup> is of the opinion that in such cases the renal calculus should be removed first, in view of the risk of an infection developing in the damaged kidney during convalescence from the operation on the other lesion. In cases of renal calculus complicated by the presence of a stone in the bladder I have removed the vesical calculus first and the renal stone at a later date.

There have been a few examples of the association of renal calculus and ureteral calculus on the same side. It is sometimes difficult to decide exactly what to do. In cases where the kidney is badly infected and dilated a nephrectomy is indicated. According to Marion it is not necessary in such cases to remove the ureteral stone, as this will remain latent. I have had one such case in which the ureteral stone was passed some time after the nephrectomy. In another case the patient passed the

ureteral calculus a few hours before the time fixed for his operation. In another case the renal stone was removed from the pelvis and olive oil injected down the ureter by a glass syringe, the nozzle of which was passed through the pyelotomy incision and fitted snugly into the upper part of the ureter. The ureter became distended and this subsided suddenly. The cystoscope was passed at the end of the operation and a small calculus was seen in the bladder lying in a pool of oil. This was passed a few days later.

I have endeavoured to give, as accurately as possible, the late results of these operations for renal calculus. It is very difficult indeed to obtain absolute accuracy of statement on such a subject unless one has the advantage of a large staff to carry out the necessary inquiries and to make the necessary investigations. There is, however, sufficient evidence to show that the frequency of recurrence after operations for renal calculus is such that it demands very serious investigation.

## PERNICIOUS ANAEMIA AND THE LIVER DIET.

BY

C. F. T. EAST, M.A., M.D. OXON., F.R.C.P. LOND.,

JUNIOR PHYSICIAN, KING'S COLLEGE HOSPITAL; PHYSICIAN, WOOLWICH WAR MEMORIAL HOSPITAL.

THE following is an account of the history of three patients treated by the liver diet introduced by Minot and Murphy<sup>1</sup> in 1926. Recent accounts from all sides are showing the good results obtained in promoting remissions in cases suffering from severe relapses. These three patients have been under treatment for a year or more. The cases are recorded in order to show what may happen afterwards.

## CASE I.

A man, aged 45, had an attack of gastro-enteritis in November, 1925, which lasted several weeks. Six months later his tongue became sore, and during the summer his throat and tongue were very sore from time to time. Early in the autumn the nausea and vomiting returned, and when admitted to hospital in October, 1926, he presented the typical picture of pernicious anaemia. His mother had had anaemia for a long time, and eventually died from it; her sister was definitely known to have died of pernicious anaemia.

Investigation showed a characteristic blood count. The blood bilirubin was high. There was complete achlorhydria. A haemolytic streptococcus was isolated from the duodenal contents, but it could not be found in the faeces. From the first he was given arsenic, and hydrochloric acid in large doses, as recommended by Hurst.

After a month in hospital he was given liver; owing to his gastric symptoms he had great difficulty in taking it, and the ingenuity of the nursing staff was fully exercised in making it palatable. In one form or another he managed to take about 5 ounces a day. An autogenous vaccine from the haemolytic streptococcus was also administered.

The improvement in the blood picture began at once, before the liver was given; this continued afterwards, especially as regards the haemoglobin. Shortly after this improvement began the haemolytic process abated and the blood bilirubin content fell, but did not reach normal limits. After leaving hospital he kept fairly well, and for a time was on his diet, and took arsenic and hydrochloric acid. After March he was able to return to work until August, when a relapse began, and the soreness of the tongue and vomiting returned. As soon as the nausea was less liver was again given, together with acid and arsenic. There was soon considerable improvement, again notably in the haemoglobin. The blood bilirubin, estimated by the van den Bergh test, fell to a low level, but the red cells improved less satisfactorily. He then left hospital by his own wish, and at home continued to take a proprietary preparation of liver similar to that which he had had in hospital.

An unfortunate relapse has again occurred, and the outlook seems far from favourable. The red cells and haemoglobin have fallen, and the blood bilirubin has again become high.

## CASE II.

A woman, aged 54, had had bouts of diarrhoea for three years, and some anaemia was noticed a year before admission. For the last four months she had had a good deal of vomiting, and had been laid up in bed. On admission to hospital she was very ill. Petechial haemorrhages were present everywhere; the heart was large and feeble, and the spleen was increased in size. There was complete achlorhydria. The teeth were septic. Five blood transfusions were given during the first six weeks, and arsenic and hydrochloric acid were also prescribed. After a little time a steady improvement set in. Before leaving hospital she began the liver diet, and since then she has taken it regularly at least

three times a week. The red cells have never returned to a higher level than  $3\frac{1}{2}$  million, but the haemoglobin has kept up to about 80 per cent. There has been a normal level of bilirubin in the blood for nearly a year. Before she went out the heart returned to normal size, and the spleen could no longer be felt. She has now felt very well for fifteen months, and has been able to do her housework.

## CASE III.

A woman, aged 33, became ill three years prior to admission, the symptoms being mainly dyspeptic. After a year she began to have attacks of diarrhoea, and vomiting became frequent; at times her tongue was sore. A year later her appendix was removed, but without benefit. The anaemia gradually started about this time; for four months she had noticed jaundice. Lately her ankles had become swollen, and she had suffered much from shortness of breath. Her mother had died of pernicious anaemia.

On admission to hospital she was seriously ill; the tongue was sore, and she was markedly yellow. The heart was very feeble and much enlarged, a gallop rhythm being audible over the mitral area. The electro-cardiogram showed heart-block, with a P-R interval of 0.32 second. There was a good deal of numbness and tingling of the hands and feet. Complete achlorhydria was present, and from the duodenum a haemolytic streptococcus was grown; this was not present in the faeces. A vaccine prepared from this organism was given.

At first a blood transfusion was given and she was put on arsenic and hydrochloric acid. Improvement in the anaemia began at once, and was most noticeable in the haemoglobin. At the same time there was a fall in the blood bilirubin, so that, on leaving hospital, it was well below the normal. Liver was not given at first as she could not take it; later, when her stomach was less troublesome, she started the diet, and has kept rigidly to it ever since—a period of ten months. She takes at least 4 ounces of liver three times a week, but lately has been using an equivalent amount of a proprietary preparation. As soon as the anaemia improved her heart returned to normal, and the heart-block disappeared. She left hospital last March, and has since kept very well. The red cells keep about  $3\frac{1}{2}$  million per c.mm., but the haemoglobin is maintained at a high level. Haemolysis has not risen above the normal limit.

During the last ten months she has had hydrochloric acid with her meals, and courses of arsenic from time to time. There has been no increase in the sensory symptoms.

## COMMENTS.

*The Administration of Liver.*

Various methods must be tried if the patient cannot take the liver easily. A paste in a sandwich of dry bread is often satisfactory. Sometimes the taste can be covered by the use of one of the strongly flavoured sauces; it goes fairly well with marmite. Small lightly boiled lumps are taken fairly easily, or it may be eaten with lemon juice or lettuce.

*The After-Treatment.*

These three cases are not of much value in illustrating the effects of the liver diet in the acute stages. It is unfortunate that there is such difficulty in getting patients to take liver when the gastric symptoms are severe.

As to the value of liver in the after-treatment, when once a remission has been secured, Cases II and III bear out the claims of Minot and Murphy,<sup>2</sup> who have had patients on liver for much longer periods than eighteen months without relapse. The first patient seems to have relapsed because for some months he neglected to take any precautions. The rather poor success subsequently seems to show that in the later relapses the treatment may be less effective. The after-treatment is unquestionably extremely important: "once pernicious anaemia, always pernicious anaemia," potentially at any rate. If, as Hurst has so often suggested, the achlorhydria is the weak point in the patient's defences, it is most important for the patient to continue taking acid. It is true that difficulties with this arise in the acute stages, when the gastric symptoms are severe and the mouth and pharynx sore; but apart from these it is usually well borne. Dilute phosphoric acid may be less effective, but is often much easier to take. It is, perhaps, too much to suppose that the artificial acid barrier can entirely replace the natural in warding off further intestinal infection. Hence it is further of the greatest importance to keep watch against sepsis arising again in the mouth and nasopharynx. The continuance of the liver diet, whatever its mode of action may be, should help in preventing any tendency to relapse.

*Prevention.*

The history of the prodromal stages in these cases has been given at some length. It is worth while to emphasize this pre-anaemic phase, during which the patient may

suffer from the symptoms of a gastro-intestinal infection from time to time, over a period of several years. If it were possible to foresee the ultimate development of the anaemic phase much might be done to prevent the later stages of the disease from occurring. The family history may give a clue. In two of these cases other members of the family had had pernicious anaemia. In the case of a fourth patient (put on liver diet too late in the last stages), who died, her mother had also died of the disease, after a remission lasting nine years.

Attacks of gastro-intestinal symptoms, with perhaps glossitis, in anyone whose family history shows pernicious anaemia, are a portent of the gravest significance. Without the family history the triad "glossitis," "gastritis," "enteritis" should warrant the examination of the gastric juice for achlorhydria. If this be found the case should be looked upon as one of potential pernicious anaemia. Liver treatment seems to be proving of real value in the acute phases, and may be of assistance in preventing relapse. But many cases might be recognized in the pre-anaemic phase, and a long and dangerous illness be perhaps prevented.

## A FORM OF SENILE SEIZURE.

BY

HUGH BARBER, M.D. LOND., M.R.C.P.,  
HONORARY PHYSICIAN, DERBYSHIRE ROYAL INFIRMARY.

WITHOUT any warning, an apparently healthy elderly person falls down unconscious. There may be some degree of clonic spasm of the face or limbs, perhaps more pronounced on one side. In a few minutes there follow loud shouting and violent behaviour, necessitating restraint, but possibly aggravated by it. After a variable time the patient regains consciousness and reason, although perhaps a little dazed and inconsequent. On full recovery of his faculties he will say that the whole incident is a blank. The whole duration of the attack is perhaps about three-quarters of an hour, but may be considerably longer. This type of emergency is seen after the event usually in hospital practice, or only in the casualty department. It does not appear to be described in medical textbooks. Of six attacks that I have witnessed the notes of the following case describe a typical example.

A railway storekeeper, aged 66, was found unconscious at 8.30 a.m. on January 24th, 1928. He was put into an ambulance, in which he became very violent, with struggling and shouting, sweating profusely. At 9 o'clock in the casualty department of the Derbyshire Royal Infirmary he was very violent, and continued so until 9.45, when he vomited twice and became conscious, but was somewhat dazed. He was taken to the ward, where he went to bed quietly, saying everything was a blank since his last duty performed that morning. Examination showed him to be a very stout plethoric man; his tongue was furred, his teeth were decayed, and pyorrhoea was present. The lungs were emphysematous; the heart was normal, but sounds distant. Temperature normal, pulse 92; artery thick; blood pressure 130 mm. systolic and 90 mm. diastolic (two days later it was 170 and 110). There were no abnormal signs in the nervous system. The urine contained a trace of albumin occasionally; but the blood urea was only 48 mg. per cent., and the urea test gave a reading of 2.4 per cent. His mind was quite clear, but the head felt heavy. The day after admission lumbar puncture revealed normal cerebrospinal fluid. Five days later he could walk about quite well.

Of six cases (five men and one woman) all were between 60 and 75 years of age. There was some evidence of cardio-vascular degeneration; but they were robust, stout, somewhat full-blooded people, engaged in their duties. There had been some degree of hyperpiesis, but no serious renal disease. In one case the disposing cause of anger precipitated the attack, but otherwise there had been no history of effort, nor were their duties arduous. In five instances the patient had come to himself in about an hour; the sixth patient, after the violence had passed off, I saw walking up and down his room with the doctor and butler in attendance. He came round about three hours

after the seizure, without any knowledge of what had been taking place. The attacks have not recurred nor have vertigo or other symptoms developed. The expectation of life has been what one would deduce from the age and cardio-vascular condition, but does not appear to have been changed by the accidental occurrence of the seizure; nor have the activities been restricted.

It would seem that the attack is due to slight haemorrhage on the surface of the brain, perhaps below the pia mater, producing coma and cerebral irritation, analogous to what may be seen occasionally after concussion. The bleeding must be quite distinct from a free subarachnoid haemorrhage: the one lumbar puncture observation revealed normal fluid. That it is a vascular lesion seems probable, because of the sudden onset, and there is the analogy of epistaxis and retinal haemorrhage occurring in this type of patient. Uræmia does not seem probable; the recovery is too complete, and the urea in the blood was not unduly high in the one case tested. The type of patient is not suggestive of epilepsy, although the analogy of a convulsion from loss of cerebral function probably holds good. A temporary oedema may be the cause, although a local aura might be expected. A localized haemorrhage, either venous or arterial, seems the most probable explanation. Embolism or thrombosis is possible, but the situation of the lesion is probably in a region where anastomosis is very free.

A SIMPLIFIED METHOD OF ARM-TO-ARM  
BLOOD TRANSFUSION.

BY

E. F. SKINNER, M.D., M.B., F.R.C.P.,  
ASSISTANT PHYSICIAN, SHEFFIELD ROYAL HOSPITAL.

THERE are so many methods of carrying out the transfusion of blood, each worker having developed his own technique, that it is almost futile to suggest a new method. However, as one who has done a large number of transfusions of all kinds and by all methods, I feel justified in making a short practical note on the subject.

There can be no question nowadays of the efficacy of transfusion as a therapeutic measure for a variety of conditions, and each clinical condition has its supporters for one or other method of carrying out the operation; but also there can be equally no question that, granted facilities, the transfusion of whole blood direct from donor to recipient is the best procedure. This was the original method, but, owing to various technical difficulties, it has long been discarded in favour of the "citrate" or "defibrinated" method.

The transfusion of whole blood is hindered by the readiness to clot exhibited by blood immediately it leaves the endothelial surroundings of blood vessels, and, of course, if blood is to remain whole—that is, to retain all its physiological and physical qualities—this tendency to coagulation must be retained. It forms one of the most important properties of blood, and in cases of haemorrhage is the one quality most desirable in the blood to be introduced. To render the blood uncoagulable by citrate appears to me a distinct disadvantage when dealing with cases of severe bleeding, and it is in such cases, particularly in obstetrical emergencies, that transfusion offers its greatest and most obvious use.

I make a plea, therefore, for the development of whole-blood transfusion, and venture to assert that with the extremely simple apparatus described below anyone who is accustomed to venipuncture can carry out a whole-blood transfusion with ease and certainty.

The apparatus consists of a syringe of 5 c.cm. capacity, with a piston of special pattern having a groove along one side. The barrel of the syringe is closed at the bottom, but has two openings in the middle opposite to each other. When in action the syringe is so arranged that by a simple turn of the wrist the groove in the piston can be put into apposition with either of the two side openings in the syringe, and either draw in or expel its contents.

The only other apparatus necessary is two pieces of rubber tubing of stout make about 8 inches long, and two needles such as are used for venipuncture, and which can be put directly into the tubing. The drawing will make

the above description clearer.

In carrying out the operation the donor and recipient are placed parallel and side by side, or head to head with feet in opposite directions, whichever is found most convenient. I usually find the two right arms best, in which case the second position is adopted.

A small table of suitable height is placed between the two couches, and on this the arms are brought close together, and the usual preparations carried out for sterilizing the skin and

making the veins prominent. Before inserting the needles I find it an advantage to fill the syringe with medicinal paraffin first, then empty it and refill it with a solution of sodium citrate, subsequently half emptying it and then leaving the piston with the groove midway between the side openings.

A needle already attached to the syringe is then inserted into the recipient's vein (this is usually done first, as it is the more difficult) and the piston turned round till the groove is opposite the recipient's opening, and if the needle is in the vein a little blood appears in the syringe immediately the piston is slightly pulled up. The piston is then turned to "midway" again and the donor's needle inserted into his vein, the same manoeuvre being carried out to ascertain whether the needle is satisfactorily in the vein.

If the venipunctures have been carried out satisfactorily, a little vaseline is smeared over the skin round the entry of the needle and the tourniquet removed from the recipient's arm. Blood is now drawn from the donor, the piston turned and pushed down, delivering the full amount to the recipient; another turn, and the blood is drawn from the donor as the piston slides up the syringe barrel; turn again and depress the piston, and the charge is delivered to the recipient, and so on.

The operation is so simple that if venipuncture has been successful 500 c.cm. of blood can be transfused in a very short time (ten minutes), and there is certainly much less reaction after this procedure than after any other.

Where conditions allow there can be no doubt that arm-to-arm transfusions should be done, and this simple type of apparatus is capable of doing the operation efficiently. It is made by Duffaud et Cie, Paris, and is the invention of a Frenchman (Dr. Joubert). It is certainly one of the most beautiful pieces of apparatus I have ever used, but as sent out by the makers it is accompanied by two or three pieces of tubing and two kinds of needles and cannulae—one for the donor and one for the recipient; to my mind these are totally unnecessary, and only tend to complicate what can be a very simple technique.

The syringes are made in two sizes—5 c.cm. and 10 c.cm.; personally I consider the 5 c.cm. the better; there is no point in using the 10 c.cm. syringe when 500 c.cm. of blood can be comfortably delivered in a few minutes with the smaller apparatus.

The syringe is not on the English market, but can be obtained from the makers direct or from Messrs. Bell and Croyden, who have promised to hold a stock of them, since when bought direct it requires about two months before they are delivered through the custom-house.

## MINIMAL RISES OF TEMPERATURE IN RHEUMATOID ARTHRITIS.

BY

L. SCHMIDT, M.D.,

MEMBER OF THE INTERNATIONAL COMMITTEE ON RHEUMATISM.  
PISTANY, CZECHOSLOVAKIA.

THERE is one type which stands out from the large group of rheumatoid arthritis cases; it is distinguished by constant though often minimal rises of temperature, and is associated with a very slow course, which is unrelenting in its progress and often defies all forms of treatment. Outwardly these cases are hardly distinguishable from those of other types.

In a discussion some years ago of pyrexia in rheumatoid arthritis I stated that "the febrile types of rheumatoid arthritis are certainly commoner than we generally assume." I presumed then that the rise of temperature in such chronic articular cases might be due to the action of toxins, and further observations have served to confirm this view to a large extent, so that I have found this a useful basis for rational therapy. Though at that time I only considered temperatures well above 98.6° F. of importance, I have gradually become convinced that minimal rises of temperature, even of only a few tenths of a degree, if continuous and not due to any other cause, are of decided importance from a prognostic as well as from a therapeutic point of view. Morning temperatures of 97.9° to 98.2° F.; which are often regarded as normal by medical practitioners and the general public, should receive serious attention in these cases, since they indicate the need for a systematic recording of the afternoon temperature. It will almost invariably be found that the afternoon temperature is above 98.6° F., and that almost without exception the accompanying signs are of serious prognostic significance.

A survey of these cases is not very cheering. The patients mostly state that they have been ill for years or at least for many months. In spite of various therapeutic measures, the pain, swelling, deformity, and atrophy of muscles and skin slowly increase. Psychological disturbances become superimposed on the organic troubles and find expression in the facies. The emaciation and obvious anaemia, which are almost constantly associated with this disability, emphasize the tragedy of the aspect.

I regard these cases of articular rheumatism with a continuous though minimal pyrexia, when there is no demonstrable focus of infection in other organs and no evidence of tuberculous rheumatism (Poncet's disease), as being due to cryptogenic bacterial lesions of polymorphic otology. The question of the primary seat of the lesion, and whether in certain cases it is the bacteria or only the bacterial toxins which invade the joints and there produce the various changes, must be left open. The important point is the entry of substances foreign to the body, or at least to the joints, into the joints and the surrounding tissues in such amounts that the irritation set up leads to various degrees of inflammation and their sequelae. The joint tissues and the surrounding fluids are thus toxic whether they take the form of macroscopic or merely of microscopic exudates and chemotactic combinations. Absorption of such substances has, according to this view, the same significance as an auto-inoculation.

It seemed that the first step towards a cure of these arthritic patients must take the form of general treatment as in the case of tuberculosis, and here a so-called "maskur" (fattening régime), carried out with great care and precision, plays an important part. Objectively improvement becomes manifest in two directions: the body weight increases, and the small rises of temperature tend to disappear, though in some cases only after a considerable time. Both these reactions are very delicate and of great prognostic significance; they usually run parallel.

Pursuing the reasoning outlined above the following conclusion was reached: When such an arthritic patient is in a negative phase and the organism is incapable of reacting it is not only useless but foolish to begin by increasing the supply of toxic molecules from the joints which the

organism is incapable of antagonizing; this is a well-known principle of all inoculation therapy. In articular rheumatism, however, just those organs are infected which, with the muscular action accompanying each movement of the body, act as a kind of peripheral pumping station, mixing the various body fluids in all directions. In these cases, more than in any others with localized lesions, movement of the joints means an increase in the inoculation of the body with toxins from the foci where they have been deposited. If, therefore, we wish to keep the body of the patient as free as possible from toxins from the joints and afebrile the further passage of toxins into the circulation must, as far as possible, be prevented by securing absolute rest for the joints—that is, by confining the patient to bed. The second essential in treatment is therefore recumbency, which, according to the individual case, is leniently or very strictly enforced.

When all that is possible has been done to facilitate the cure by a fattening regime and recumbency, the patient must be guarded from the various harmful forms of treatment which are sometimes warmly recommended. I refer particularly to the routine ordering of massage for such cases. I regard daily massage in these subfebrile cases as a grave error, analogous to repeated injections of tuberculin in febrile cases of tuberculosis. The same applies to the often indiscriminate use of diathermy and radiant heat. In balneological treatment mistakes are also too often made in these cases, when, regardless of the thermo-sensitive nature of the case, and irrespective of general or local reactions, the patient is allowed to continue his baths without rest or intermission, and is not granted time or opportunity to pass from the negative phase to the positive phase of improvement. The result is fatigue and exhaustion of the organism instead of beneficial stimulation; the condition remains stationary or becomes worse, whereas a rational plan of treatment adequately pursued might achieve improvement or even complete cure.

The line of thought which I have indicated in this paper has proved a sound working hypothesis in practice.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### A CASE OF VOLVULUS NEONATORUM.

THE following case seems of sufficient interest to be placed on record.

A male child, aged 4 days, was admitted to the South Eastern Hospital for Children, Lower Sydenham, with a history of vomiting green fluid since birth and of passing dark motions which, the evening before admission, had turned to fluid blood; this being passed continuously and in some quantity. He was a full-time child, large and well developed, and weighed 8 lb. 8 oz. He was not greatly distressed, the fontanelles were not depressed, but pallor was marked. Pulse 148, respirations 46, temperature 98.2° F.

On examination the abdomen was soft and the stomach slightly distended; nothing was found on palpation. Blood leaked almost continuously from the rectum, but on rectal examination nothing abnormal was discovered.

The following day the condition remained much the same, but the temperature rose to 100.6° F. in the afternoon; the flow of blood from the rectum was much less. No food was retained owing to persistent vomiting, and there was no obvious distension of the abdomen. The child died the following morning.

**Post-mortem Examination.**—The abdomen showed a slight distension. On opening, a small quantity of dark blood was found, and presenting in the incision was a mass of coagulated blood. On further examination it was found that the stomach and duodenum were normal, that just beyond the duodeno-jejunal junction there had been an anti-clockwise rotation of the small bowel, so that this upper portion was tightly wrapped round the last portion of the ileum just above the ileo-caecal valve. The mesentery was, practically speaking, absent, being represented by a fibrous cord containing the superior mesenteric artery, over the front of which passed the duodenum, and which was (that is, the artery) constricted by the volvulus. There was therefore a complete strangulation of the whole of the jejunum and ileum, leaving the stomach, duodenum, and the whole of the large bowel looking quite normal. The rest of the organs did not show any abnormality.

Mr. Norman M. Dott has written at length on the subject of anomalies of intestinal rotation in the *British Journal of Surgery* (1923, vol. xi), and in the *British*

*Medical Journal* of February 5th, 1927 (p. 230); he has described a case of volvulus neonatorum which was successfully diagnosed and treated by operation, a result of the application of theory and study to practice which must have afforded him considerable satisfaction. The case he describes, however, differs from the above in several details; the absence of mesentery and the anti-clockwise rotation of the bowel are similar, but he describes the stomach and duodenum as being greatly distended, and the small bowel collapsed and cyanosed. This case, then, must be regarded as unique in the acuteness of the symptoms and the degree of vascular obstruction.

Our thanks are due to Mr. Dott for his interest and help in this case.

GILBERT W. CHARSLEY, M.B., Ch.B.,

Honorary Physician,

GEORGE RICHARDSON, M.D., F.R.C.S. Ed.,

Honorary Pathologist,

South Eastern Hospital for Children.

#### EMBOLISM OF APEX OF LUNG.

EMBOLISM of the lung is fairly common, but if the apex of the upper lobe of the lung is involved, difficulty in diagnosis may arise. These notes on a case recently attended by me may therefore be of interest.

An unmarried woman, aged 40, had suffered from exophthalmic goitre for many years, but had managed to do her work as a bookish clerk at a hotel, and had received no medical attention for two years. On December 25th, 1927, she was suddenly seized with shortness of breath and severe incessant coughing; she vomited her last meal and coughed up some bright red blood. She was first seen by me half an hour after the onset of these symptoms. Her pulse was about 140, she looked very ill, and the cough was incessant. She was given a small dose of morphine hypodermically, and a sedative for the cough. Restlessness was a marked symptom.

The next day many coarse râles were audible over the apex of the right lung, with bronchial breath sounds and markedly impaired resonance. She was still coughing up a little bright red blood; the temperature was 101° F. The heart's apex beat was two inches outside the nipple line. Her chief complaint was of the troublesome cough. The sputum was examined for tubercle bacilli with negative result. The systolic blood pressure was 160 mm. Hg, with negative result. The pulse rate 120 a minute, but with a few drops of Lugol's and the pulse dropped to 80 and the blood pressure to 145 mm., the apex beat of the heart coming to lie in the nipple line. She could only take 1½ minims of Lugol's solution three times a day; larger doses caused coughing attacks. With rest in bed for a fortnight she lost her cough completely and the physical signs at the right apex of the lung cleared up entirely. She still had a systolic murmur at the apex of the heart continued into the axilla.

Swanage.

W. A. REES, M.D. Lond., F.R.C.S.

#### DYSPHAGIA ASSOCIATED WITH ANAEMIA.

THE following case is similar in many points to the clinical type described in the article by Drs. Jones and Owen in the *Journal* of February 18th (p. 256), but the anaemia has been megalocytic ever since the patient came under my care in January, 1926.

A married woman, aged 50, complained of weakness, shortness of breath, and inability to swallow, unless the food was finely minced, and of soreness of the tongue and lips, for "years." She said she had been anaemic from girlhood, and at the time of the menopause she suffered from melancholia and was in an asylum. The difficulty in swallowing was worse sometimes than at others. At times she could only manage fluids—solid food seemed to stick, and she almost choked till she got it up again.

She was of a lemon yellow pallor with slight malar flush, the lips pale, with sore areas at both corners of the mouth; the artificial teeth for many years. The spleen was palpable, the liver also was slightly enlarged. The blood count was as follows: liver cells 1,410,000 per c.mm., haemoglobin 44 per cent., colour index 1.5, white cells 4,800 per c.mm. The films showed no nucleated red cells, marked poikilocytosis and anisocytosis, with many megalocytes. The coagulation time of the blood was prolonged: the blood of a normal control took 2 minutes 15 seconds to clot in Gibb's coagulometer, while the patient's blood took 2 minutes 45 seconds.

The patient improved a little on arsenic and hydrochloric acid after meals, but she would not persist with the acid as it increased the soreness of her mouth, even when well diluted. Latterly she has improved very much on liver, which she takes minced three times a week. She is now able to do most of her housework and goes out for short walks. Her red cells are now 2,630,000 per c.mm., but the colour index is still above unity.

## CLINICAL AND SCIENTIFIC PROCEEDINGS.

## MONMOUTHSHIRE DIVISION.

*Recent Changes in Obstetrical Practice.*

At a meeting of the Monmouthshire Division held at the Royal Gwent Hospital, Newport, on March 9th, with the chairman, Dr. W. D. STREE, presiding, a lecture on some recent changes in obstetrical treatment was given by Dr. LESLIE WILLIAMS, Queen Charlotte's Hospital, London.

Dr. Leslie Williams dealt first with the 2-unit dose of pituitary extract, which he regarded as one of the greatest recent advances in obstetrics, and as calculated to reduce the incidence of puerperal sepsis, and to limit the use and abuse of forceps. The introduction of this new treatment was due to one of his colleagues at Queen Charlotte's Hospital, and according to his observations, both experimental and clinical, the drug in 2-unit—for example, 0.2 c.cm.—doses, might safely be given at any period in labour. The speaker believed the ideal use was in a normal labour when the first stage had been allowed to progress under some sedative drugs such as morphine and scopolamine, and when the pain of the second stage had been controlled by chloroform. In these circumstances the expulsion of the child was apt to be tedious, and an intramuscular injection of 0.2 c.cm. pituitrin would result in a great increase in the power of the uterine contractions and the spontaneous delivery of the child. If necessary, the injection could be repeated. The patient should be well under chloroform before the injection was given, as otherwise intense and sometimes almost continuous pain was caused by the powerful uterine contractions. In his experience the child was not harmed in any way, though the foetal heart rate was unquestionably affected. The small dose of pituitrin was even more valuable for cases of secondary inertia with the head well down. The presence of even minor degrees of disproportion between the foetus and the pelvis contraindicated the administration of pituitrin. Its use, however, during the second stage in suitable cases did not appear to predispose to hour-glass contraction, with retention of the placenta.

With the use of this drug during the first stage, as a rule, the uterine contractions were increased in power and duration, and furthermore were regularized. In cases of a slowly dilating cervix with painful colicky uterine contractions, his personal preference was to give morphine and scopolamine and allow the dilatation to proceed spontaneously, giving further doses of 1/400 gr. of scopolamine at intervals of a half to one hour if required. Should the dilatation still be proceeding poorly he would have no hesitation in giving a 2-unit dose of pituitrin as well, and repeating if necessary.

*Treatment of Puerperal Sepsis.*

Proceeding to discuss puerperal sepsis, Dr. Williams said that in the light of present knowledge the treatment of puerperal sepsis must be preventive—by careful preparation of the perineum and vagina, by efforts on the part of the accoucheur to be surgically as clean as if he were performing an abdominal section; by the avoidance of "meddlesome midwifery," and particularly the avoidance of manual removal of the placenta. He felt confident that a great improvement in obstetric technique in the country generally would result from the present tendency to raise the status of obstetrics in the student's curriculum. As things were they all had certain cases of puerperal infection. In his experience no improvement could be expected from the prophylactic use of vaccines, or serums, or the two combined. In dealing with a case of puerperal infection the first duty was to decide whether the case was one of uterine (or cervical or perineal) infection which had not been kept within bounds by the local defensive mechanism, but had invaded the blood stream—"septicaemia"; or was one in which the infection had been localized and there was merely the absorption of toxic products of the local suppuration—"toxaemia." The former was treated by methods designed to raise the patient's bactericidal power, while the treatment of the

latter was local. To distinguish between the two conditions was not easy in all cases. On clinical grounds a blood infection was to be suspected if the disease was early in onset, marked by repeated rigors, a high degree of fever, and a rapid pulse; they should not be deceived by the patient's subjective sensation of being in good health. The final proof of a blood infection was obtainable only by a positive blood culture, and they were fortunate in the improved bacteriological technique of to-day, in that a positive result was obtainable in most cases. The treatment of such a proved case was briefly this: Absolute rest in bed in the open air; plenty of good food, as solid and substantial as the patient felt she could deal with; the avoidance of drastic purgatives, but gentle daily enemata if required; plenty of fluids; and, lastly, those special steps designed to increase the bactericidal power of the blood. Here weekly intravenous injection of some of the "606" preparations, in doses of 0.4 to 0.6 gram, were valuable. Of equal importance was the transfusion of whole blood—small amounts, say 10 to 12 oz., repeated once or twice a week. The value of these injections might further be increased by artificially producing a leucocytosis in the donor by a morning injection of 2 c.cm. of sodium nucleinate, and making the transfusion from him in the afternoon during the period of the increased leucocyte content of his blood. The variety of treatment suggested for puerperal septicaemia clearly indicated the inefficiency of these measures. His personal experience, however, led him to believe that there was some value in these treatments by blood transfusion and the salvarsan preparations.

In localized infection it was, of course, obvious that the site might be uterine, cervical, vaginal, perineal, etc. The principles of treatment were, first, hygienic—fresh air, sunlight, and good nourishing food—and secondly, cleansing and drainage of the infected area. In the second matter they owed much to Dr. Remington Hobbs. The speaker was a very firm believer in the efficacy of the intrauterine glycerin treatment which Dr. Hobbs employed to promote "tissue drainage." For uterine and cervical lesions the hygroscopic action of the glycerin, together with the free drainage secured by the diminution of the oedema of the mucosa of the uterine and cervical canals, had proved of the greatest value. For the more superficial lesions, such as an infected perineal tear with septic absorption, the removal of stiches and local cleansing would suffice. He wished to lay it down as an axiom that the infected puerperal uterus must in no circumstances be touched with the eurette, and might be cleared out by a gloved finger only if haemorrhage, as well as the probability of retained products, rendered this a necessity. In the absence of haemorrhage he had no hesitation in advising Fowler's position, pituitrin, and ergot, in preference to any operative procedure.

*Concealed Accidental Haemorrhage.*

In cases of concealed accidental haemorrhage it appeared that obstetricians might, in the past, have been the direct cause of death by the violence of their treatment. They had tried to "hog" the practically paralysed uterus into contractions by means of vaginal plugging, tight binders, pituitrin, etc. It was now realized that the essential factor in the case was not the amount of the haemorrhage, but the degree of the shock. *Post-mortem* examination of a fatal case of this disease disclosed a bruised "coppery" uterus with the muscular fibres separated by interstitial haemorrhages, a retroplacental haematoma, haemorrhages in the broad ligament and in the retroperitoneal tissues. But the total amount of blood lost was only between, say, 1/2 and 1 pint. Incidentally, she was also suffering from one of the pregnancy toxaeemias, but the condition demanding treatment was the shock. She should be kept still in bed, kept warm, and given enough morphine to produce obvious effects. If she improved it was because the shock passed off. Simultaneously the uterus would begin to recover its tone and she would start bleeding externally, the concealed blood being expelled by the uterus regaining activity. This was the time further to urge the uterus to effort, and when the shock had passed off and was not likely to be renewed by obstetric efforts, to plug the cervix and vagina, to put on a tight binder, and to give small repeated doses of pituitrin. As soon as the contractions

became at all good and regular: the first plug was removed, the membranes ruptured, and a fresh plug introduced if this was still necessary. If, however, the patient's condition showed no sign of improvement, but became worse, then Caesarean section should be performed without further loss of time. After the child had been extracted—stillborn, of course—the uterus might contract or it might remain absolutely inert. In the former case the placenta and membranes were removed and conservatio Caesarean section was completed in the usual manner; but if the uterus remained limp and flaccid every effort must be made to make it contract. It should be wrapped and massaged in hot towels, and injections of pituitary extract should be made into its musculature. If these efforts were successful then again conservatio Caesarean section was completed. But if the uterus persisted in remaining a bleeding mass of bruised and completely relaxed muscle, then hysterectomy must be performed immediately. If was, of course, a rather desperate business to have to perform a formidable operation on a woman who was already in a very dangerous condition. But his own limited experience led Dr. Leslie Williams to take a more hopeful view of such a case than was indicated by the percentage mortality rate usually quoted.

## Reports of Societies.

### PRESENT POSITION OF RADIUM THERAPY.

At a meeting of the Section of Electrotherapeutics of the Royal Society of Medicine on March 16th, Sir HENRY GAUVAIN presiding, a discussion took place on the present position of radium therapy.

Mr. HARWARD PINCH, director of the Radium Institute, in an opening address, reminded the Section that it was now thirty-two years since Henri Becquerel read his paper on an invisible radiation emitted by salts of uranium, and thirty years since the investigations by the Curies began. Radium at first had purely non-medical applications, but after a time it began to be used by French medical men in the treatment of superficial lesions, a surface reaction being obtained which varied in degree from a mild erythema to a definite ulceration. The next stage was the use of radium salts enclosed in tubes and inserted into easily accessible tumours; the results were encouraging, and presently the help of the surgeon was solicited and an elaborate system of surgery of access was practised. The latest development of all, and an extremely important one, was the use of "seeds" of screened radium emanation or "radon." Several years ago the use of unscreened emanation seeds was tried, but they were found to have an intense necrotic action and to cause pain, and therefore were given up. Screening did away with these disadvantages, and the results were really surprising. The proportions of alpha, beta, and gamma rays in a specimen of radium might be set out as 10,000, 1,000, and 100 respectively, and the alpha rays could be disregarded therapeutically. Of the beta radiation, 94 per cent. was absorbed by 1 cm. of body tissue, so that these rays were most effective when applied in superficial therapy. Complete absorption of the gamma rays by the body never occurred. Of the patients with superficial lesions who came to the Institute, fully 98 per cent. were treated either with unscreened rays or with one of four screens—namely, 0.01 mm. of aluminium—an extremely thin filter—0.01 mm. of lead, which let through 28 per cent. of the beta radiation, and 0.5 and 1 mm. of silver, when it was desired to act on the deeper layers of corium and subcutaneous tissue. Mr. Pinch then showed a number of photographs of cases illustrating the improvement which had resulted in conditions such as psoriasis, lupus, and keloid after radium applications. One case was of mycosis fungoides of the abdominal wall which showed what might be called a specific reaction to radium. He did not claim that the method of application employed at the Institute was the only one which could be used with good effect, but it had certainly passed the test of a long clinical experience.

Deep radium therapy he defined as the treatment of disease by prolonged exposures with radium or "radon" apparatus so screened as to emit a preponderant hard beta and gamma or gamma radiation only. The best standard screen for getting the gamma radiation only was 1 mm. of platinum, which cut out all beta radiation, and transmitted 90 per cent. of gamma. But platinum was an expensive metal, especially when used for large surface applicators, and an equivalent filtration was provided by 2 mm. of lead, lead being of approximately half the density of platinum. Deep radium therapy might be carried out by three methods: (1) externally, by tubes or other applicators, either in contact or at a distance; (2) by employing surgery of access so as to apply the radium to the growth from a more advantageous position; (3) by embedding screened emanation seeds, using a technique which he described and illustrated. At the Radium Institute contact radiation was chiefly used—in the treatment of breast cases, for example, 3 mg. of radium element, with a filter of 2 mm. of lead, in actual contact was a medium dose. The disadvantage of the inverse square law, whereby the radiation diminished with depth, was countered as far as possible by the crossfire method. Very little distance radiation was carried out at the Radium Institute, though it was largely used on the Continent. The speaker illustrated the enormous difference which a separation of 10 cm. between the skin and the applicator made in the radiation reaching the tumour. There was, however, one form of distance radiation which had been very useful—that was the placing of radium tubes containing 50 to 75 mg. in a mould of wax compound for the treatment of glands of the neck.

There were extreme schools among radiologists, some of whom believed in the use of large doses for a short time, and others the use of small doses for a long time. The pendulum had swung over from the former to the latter, and there were many who advocated small doses given for a great length of time, as though that were the only method of any value. Mr. Pinch denied this, believing that there were many cases in which excellent results could be obtained with a large quantity of radium used for a short time. Lymphosarcoma and other conditions responded best to this method, while, on the other hand, slow-growing squamous-celled epitheliomas responded best to small quantities applied for a long time. Between these extremes there must be many conditions where the optimum would be some more equal distribution of the two factors, quantity and time.

Treatment by burying screened emanation seeds had several distinct advantages. It involved very little traumatism, and usually necessitated only local anaesthesia; as the seeds were charged only with emanation it was no great matter if they were lost; and the container, being made of platinum, did not corrode. Mr. Pinch showed photographs of a number of cases of improvement resulting from radium in deep-seated conditions. One case was in an octogenarian who had an epithelioma of the ear, the size of a lemon. Thirteen seeds were buried, and within four weeks the whole growth had disappeared. Another case was that of a woman who came in the most miserable condition with an epithelioma affecting the faucial pillars and the epiglottis, and running a little way out of the pharyngeal wall. Here tubes were buried, and the effect after six weeks could only be described as miraculous. In a rapidly growing epithelioma of the anal canal, so painful that examination without an anaesthetic was impossible, thirteen seeds were inserted, and six weeks later the rectum could be examined with perfect ease, and there was not a sign of growth remaining.

Mr. Pinch concluded with a word of protest and of prophecy. He said that there was a certain section of medical men who were rather inclined to depreciate the work accomplished by British radiologists. They talked in rather superior manner of what some professor or other was doing in Paris or Vienna. He took exception to that. While yielding to no one in his admiration for what was done on the Continent, he submitted that there had been extremely good, even epoch-making, work done in this country, and that British surgeons and radiologists

deserved credit. His prophecy, which he made deliberately, after the fullest consideration, was that in the very near future radium would form as necessary a part of the up-to-date surgeon's armamentarium as the scalpel, and it would be possible by this means to handle with confidence and success many cases of malignant disease which at present were regarded as inoperable and hopeless.

The discussion which followed was somewhat curtailed owing to the length of the opening address; Mr. Hayward Pinch had intended only to speak for half an hour, but his remarks were of such interest to the very large audience that they repeatedly bade him "Go on," so that his address was extended to an hour and a quarter. A few speakers, however, contributed their experiences.

Dr. EDGAR HAYDON (Newton Abbot) spoke of favourable results which he had seen in oesophageal carcinoma from placing tubes containing 4 mg. of radium around the growth, and burying seeds within it.

Dr. WILLIAM HILL was strongly against burying radium seeds in oesophageal growths, which he thought a dangerous practice on account of the possibility of perforation. He had, however, exposed over a hundred such cases to radium. One case had lived for seven years, and at least one-third had been distinctly relieved and their lives prolonged.

Dr. DOUGLAS WEBSTER endorsed Mr. Pinch's disapproval of those who wished to lay it down as a law that small doses must be given over a long period. Very successful results had followed from the application of large doses for a short time. Kelly of Baltimore had even applied a gram of radium on superficial growths for a matter of a minute or two. French workers, on the other hand, insisted that cases must be treated with very small doses for days or for a week or more. The speaker believed that treatment from a distance was useful in certain cases. Middlesex Hospital was fortunate enough just after the war to have a loan of 5 grams of radium, though it was very quickly broken up and sent to other centres, and he, for a time, was able to have the use of 0.5 gram of radium element. Using this at a distance of 6 cm., the dose being twenty-five hours, divided up on different days, he found the results very good in breast cancer and supra-clavicular recurrences.

Dr. F. HERMAN-JOHNSON believed the burying of radium seeds to be an important method of the future, but he hoped that enthusiasm for radium would not blind radiologists to other factors. In the country as a whole there was not nearly enough radium for the treatment of cases, and, however striking the results with radium, many of those shown by Mr. Pinch could be paralleled by those obtained with x-ray treatment, both superficial and deep. A judicious combination of x-ray treatment, diathermy, and other measures would enable a great many conditions to be dealt with for which radium supplies were inadequate, although radium, could it be obtained, might give a more speedy and cosmetic result. Moreover, in all this local treatment by radium the general condition of the patient should not be lost sight of. He had found many patients come to the x-ray department for treatment for recurrences, and, after doing well for a time, appear to come to the end of their response. Formerly these people were dismissed with an intimation to their doctor that nothing more could be done, but now he adopted different tactics, and sent some of them for light treatment, whereby they regained their response in a remarkable manner. It appeared to him that light treatment, properly applied, provided a means of picking up the patient's response and giving him a new lease of life.

Dr. G. VILVANDRE contested some of the statements of the last speaker, and said that in the treatment of epithelioma he had found radium much more valuable than x-rays. In his hands the latter had been a failure in that condition.

Sir CHARLES GORDON-WATSON had hoped to hear more about the surgery of access. For the last three years he had been dealing with carcinoma of the rectum by the so-called surgery of access—that was to say, he had been taking growths which were too advanced for excision, and trying to get them thoroughly exposed as far as possible by surgery; then he measured up the growth in cubic milli-

metres, and for every cubic millimetre of growth applied 2 mg. of radium. The whole problem was that of the optimum dose in the particular case. One woman with a very advanced growth, and who was extremely cachectic and ill, had 50 mg. inserted for seven days; she underwent a very severe reaction, but when she improved she did so with great rapidity. What was wanted was a mode of radium application giving parallel rays to every part of the growth.

Mr. M. H. OLDERSHAW suggested that the difference in behaviour to radium as between rapidly growing and slow-growing tumours—the former doing better with a large dose applied for a short time, and the latter with a smaller dose for a longer time—might be due to the special susceptibility of the cancer cell to the action of radium during the process of division. The aim should be to obtain as uniform a radiation as possible through the tumour at a time which would catch every cell when dividing.

Dr. J. E. A. LYNHAM urged that in hospital radium equipment, in addition to needles and tubes, there should be flat applicators, which were extremely useful. He also reported good results from a combination of x-rays and radium. Sir HENRY GAUVAIN raised the question as to the possible dangers of radium treatment. In the early days of x-ray treatment the rays were used very largely for such conditions as lupus vulgaris, with results which were now known to be deplorable. Were such results to be anticipated with radium, or were there any dangers with radium of which users should be aware?

Mr. HAYWARD PINCH, in a brief reply, said that he had not attempted to insert seeds in the oesophagus. With regard to the different response of different tumours, the supposition was correct that all cells were more vulnerable to radiation during the process of division.

## SARCOMATOUS METAPLASIA OF A UTERINE FIBROMA.

At a meeting of the North of England Obstetrical and Gynaecological Society at Sheffield on February 24th, the president, Dr. LETHA MURRAY, described a case of sarcomatous metaplasia of a fibroid tumour.

Dr. Murray said that the subject of malignant metaplasia in fibroid tumours had interested him for many years. In the literature its incidence was given as between 1 and 2 per cent., while Eden and Lockyer thought that it should be slightly under 1 per cent. Dr. Murray believed that he had cut representative sections from every fibroid that he had ever removed, but the present case was the first definite malignant metaplasia occurring within a fibroid that had ever come his way. This struck him as a remarkable contrast, and suggested that there must often have been an element of doubt in the diagnosis. In all likelihood the chance of error in diagnosis had been increased by including fibroid polypi. On four occasions in his experience an oedematous fibroid polypus had shown a microscopical appearance rather suggestive of malignancy; cytological examination, however, coupled with complete absence of recurrence in any one of these cases, made it quite certain that the oedema was the cause of the doubtful appearance. The society had taken its part in reporting specimens; it had to be noted, however, that two of the three were queried when they were shown. Most of the cases recorded by members and others had been associated with rapid growth and blood-stained discharge from the uterus. This latter sign suggested that the tumour, if it really began in a fibroma, had partially escaped therefrom; there was a loophole for error, inasmuch as a uterine sarcoma, arising, for example, in the endometrium, might penetrate an adjacent fibroid growth. The case he recorded showed a sarcoma arising in the centre of a fibroid tumour which had been removed by myomectomy. The malignancy was not suspected until the specimen was incised after operation. A further point of interest lay in the youth of the patient.

A woman, aged 29, who had been married for seven years, had one child six years old. She had had aching pain in the right side off and on for twelve months; menstruation (5/28) had been regular and moderate until one month before she came under notice, when, four days after an ordinary period, a further and

similar period occurred. Examination showed a rounded and enlarged uterus, the fundus being palpable two inches above the symphysis pubis. A diagnosis of fibroid uterus was made and a solitary fibroid, weighing 12 oz., was enucleated from the right wall of the uterus at the fundus through an anterior incision. There was at first slight difficulty in defining the capsule anteriorly, but not more so than occasionally happened with myomectomy operations. The uterine cavity was accidentally opened during the enucleation and was sutured. The specimen had the external appearance of an ordinary fibromyoma. A preliminary incision of the specimen showed in the centre a soft red and pulpy area, completely surrounded by fibromyomatous tissue; a hemisection was postponed until the specimen had been hardened. There was a complete layer of pale fibroid tissue beyond the central growth, which at no point had reached nearer the capsule than a quarter of an inch. Microscopical examination showed a core of haemorrhage and necrosed tissue, with malignant areas at the periphery. These areas were definitely cellular and appeared to have vascular relations.

Dr. Murray thought the growth might well be called an endo- or peri-thelioma. It resembled very much a specimen described and figured by Leith;<sup>1</sup> the growth, in that case, occurred in a woman aged 44, and two years after the menopause. Presuming that there would be agreement that this was in fact a case of sarcomatous metaplasia, he asked whether he should now remove the uterus. The patient, so far, remained fit and well.

Dr. A. A. GEMMELL (Liverpool) recorded a case of sarcomatous metaplasia of a fibroid growth which illustrated some of the difficulties in forming an opinion on the origin of the sarcoma.

The patient was 54 years of age and had not reached the menopause. She had had four children. Menstruation had been excessive for the last twelve years, and she had been losing continuously for four months when she came for consultation.

The specimen consisted of the uterus and both appendages, removed by total hysterectomy. It weighed 2½ lb. and measured on removal 5½ by 4 by 4 inches. It was regular in outline, with adhesions of omentum to its anterior surface. The uterus had been opened anteriorly and showed a growth projecting from the posterior surface into the cavity and filling it; the lower pole was necrotic and had burst. On section the tumour was mainly whitish and soft in appearance, with areas of yellow coloration and some haemorrhages. Sections showed the growth to be almost entirely a sarcoma of mixed cell type, composed of fairly large spindle cells with numerous larger "giant cells" of varying size, many ovoid or polygonal, and containing one, two, or three nuclei. Remnants of the fibroid structure were visible in places both at the periphery and among the sarcomatous cells. Sections of the uterine muscle at the base of the tumour failed to show any sarcoma, as did sections of the endometrium close up to the point where the tumour had ruptured.

Dr. Gemmell said that Whitridge Williams's article of 1894 still remained amongst the best of those on the histogenesis of sarcoma of the uterus. Judged by his standards, the present case was not likely to have originated in the endometrium, since that membrane was normal right up to the place where the necrotic portion of the tumour had ruptured, and also because the muscular uterine wall maintained its normal thickness. It might have arisen from the uterine wall, but the presence of myoma-like tissue amidst the sarcoma cells and at the periphery of the tumour opposed this view. That the tumour was apparently circumscribed did not exclude the uterine wall as a possible origin. On the other hand, this myoma-like tissue might be merely remnants of the connective tissue of the uterine wall. The history of excessive menstrual loss for twelve years was, however, suggestive of a pre-existing non-malignant condition.

#### Uterine Carcinoma Following Operation.

Mr. W. GOUCH (Leeds) described a case of carcinoma of the body of the uterus after interposition operation for genital prolapse.

The patient, aged 70, complained chiefly of urinary symptoms, dysuria, and pain, and there had been haemorrhage in the urine for the previous month. There was also complaint of bearing-down pain in the lower abdomen and back. Amputation of the cervix, colporrhaphy, and vesico-vaginal interposition had been performed fifteen years previously. Since that time she had been under the care of another surgeon, suffering from obscure urinary symptoms. There was marked atrophy of the vagina, and no symptoms. There was a hard mass lying posterior to cervix could be felt. There was a hard mass lying posterior to the urethra and extending to the base of the bladder. It was the fact that he knew that the surgeon who had operated on her for the genital prolapse was in the habit of performing the interposition operation that made him suspect this mass to be the body of the uterus. Investigating the condition under anaesthesia he found the anterior vaginal wall invaded by growth which had ulcerated through about half an inch above the urethral meatus. The bladder was enlarged and extended well

above the pubes; the urethra was not affected. Microscopical examination of the growth showed it to be a papillary adenocarcinoma of the corporeal type on the whole.

#### Full-term Ectopic Gestation.

Professor W. FLETCHER SHAW described a full-term ectopic pregnancy in a primipara; labour pains were said to have begun five weeks after the expected date of the confinement. After twenty-four hours the pains ceased, and did not recur, and from that time she felt no foetal movements. He saw her four months later and made a diagnosis of ectopic pregnancy. At the laparotomy he opened a large sac containing a full-term foetus, nacerated and foul-smelling. He removed most of the placenta, but left behind those parts which were firmly adherent. The abdomen was closed with a large packing of gauze in the cavity. The patient had a raised temperature for three weeks, but was fit to go home at the end of six weeks. She was now quite well, but a small sinus remained.

Mr. ST. GEORGE WILSON (Liverpool) recorded a case of full-term ectopic gestation treated by Caesarean section, with delivery of a living child. He had seen the patient first when she was seven months pregnant, and a diagnosis of ovarian cyst complicating pregnancy was made. An x-ray examination at term showed the foetus lying above the pelvic brim, and in an unusual attitude. Ten calendar months after the last menstrual period she reported at hospital, complaining of labour pains and a "show." Abdominal section showed that the condition was an extra-uterine pregnancy, apparently situated in the right broad ligament. The placenta was left *in situ*, the cord was cut short, and the incision in the sac wall was closed. The abdominal wall was sutured without drainage. The tumour in the abdomen was then about the size of a uterus of twenty-two weeks' gestation. The temperature remained raised for three weeks, but the patient was discharged at the end of the fourth week. By this time there had been little diminution in the size of the abdominal tumour. The child weighed 5½ lb., and had numerous deformities; it lived for five months. Recent examination of the mother showed a swelling about the size of a hen's egg to the right of a normally situated uterus.

#### Combined Concealed Accidental and Unavoidable Haemorrhage.

Dr. F. H. LACEY (Manchester) described a case of combined concealed accidental and unavoidable haemorrhage.

A 4-paræ, aged 33, was seen when thirty-seven weeks pregnant, with a history of vaginal haemorrhage. Although this had been slight, yet her general condition suggested that it had been severe. She was pale and faint, and the pulse was 120 and weak; she was somewhat restless and complained of no definite pain, but she was somewhat aching in her abdomen, and of dizziness which had of a continual ache in her abdomen, and of dizziness which had been present for about seven hours. There was marked albuminuria. The abdomen was very large, tense, and tender, particularly to the right of the fundus; foetal parts were felt indefinitely, but foetal heart sounds could not be heard. On vaginal examination the os admitted one finger and the placenta was felt to be covering it, but Dr. Lacey was confident from her condition that she had a concealed accidental haemorrhage, and decided to perform Caesarean section.

On opening the abdomen the uterus was found to be very distended, but there was no evidence of haemorrhage into the wall. Incision of the uterus released a large quantity of amniotic fluid, and the cavity was seen to be occupied by twins; one placenta and the lower uterine segment, while the other one was on the posterior wall of the uterus, under which, and close to the edge, was about a quart of clots. The uterus was removed. The twins weighed 6 lb. and 5½ lb.; the former was attached to the placenta prævia, and lived for forty minutes, whereas the other child was stillborn. The mother made an uneventful recovery. On account of the concealed haemorrhage the blood was examined and the Wassermann reaction was found to be strongly positive. The patient therefore had marked albuminuria, hydræmniot, twins, concealed accidental haemorrhage, placenta prævia, and syphilis.

#### An Occasional Symptom of Uterine Cancer.

Professor MILES PHILLIPS (Sheffield) read a note on intermittent periodic pain as an occasional symptom of carcinoma corporis uteri. He said that Sir James Simpson, the discoverer of chloroform, first drew attention to this symptom at a meeting of the Edinburgh Obstetrical Society in 1863. After demonstrating a specimen of carcinoma of the body of the uterus Professor Simpson had referred to the daily recurrence—usually at a regular hour—of intense paroxysms of pain, perhaps slight at first and intermittent, but soon reaching a high pitch of intensity, continued for an hour or two, and then gradually sub-

siding. He also said that this symptom had been very marked in most of the cases of cancer of the uterine body which had come under his observation. He specified one instance in which severe hypogastric pain began at 12, 1, or 2 o'clock in the day, culminated between 3 and 5 in the afternoon, and ceased at 6 or 7. On some days it returned again from 10 p.m. to midnight. In this case, after dilating the cervix with spongio tents, Professor Simpson had scraped away a friable growth, but the periodic pain still continued in the afternoons, and his final note stated that the patient was "dismissed to-day as her cries were injurious to the other patients and as there was no prospect of giving her relief." He had seen similar intermittent periodic pains in a case of calcified submucons fibroid, and somewhat similar paroxysms of pain in a few instances of retention of fluid in the cavity of the uterus from occlusion of the os. Finally, he stated that, except in those rare cases, the symptom he had tried to describe was only to be met with, so far as his observation went, in patients who were suffering from carcinoma of the body and fundus of the uterus. Professor Miles Phillips said that this symptom was not often mentioned by English writers, for the reason, he believed, that it was not often observed. Eden and Lockyer (*Gynaecology*, 1928), in describing the symptoms of corporeal cancer, did not refer to pain of any description. This appeared to Professor Phillips to be very remarkable, as in his own series of eighty-two cases, which he had recently analysed, pain was definitely present in sixty (73 per cent.). However, Thomas Wilson in the *New System of Gynaecology* said "Simpson described as an early symptom in these cases regularly recurring attacks of severe colicky pain in the lower abdomen. This would appear to be rare, and I have only seen one such case. The pain is described as a severe bearing down, and appears to be due to efforts of the uterus to expel the cancerous tumour from the cavity." Winter and Ruge in *Gynaecological Diagnosis* stated that another very suspicious and almost pathognomonic symptom was found in Simpson's pains—namely, regularly labour-like pains, lasting several hours and recurring at a definite time of the day. Pozzi, in his treatise on gynaecology, also recalled that Simpson first drew attention to the remarkable paroxysmal pains which occurred at regular intervals. But Pozzi disagreed with some writers, including Schroder, who had stated that these pains were due to spasmodic expulsive efforts, because he had noticed that they still continued after he had scraped away the friable growth. He believed that the pain was a true neuritis resulting from involvement of the nerves supplying the uterus. A recent case in which this symptom was well marked had led Professor Miles Phillips to hunt through his records of cases of corporeal cancer. He had a clear recollection of two instances of Simpson's pain, but his notes revealed two others, so he could record five in all out of a series of eighty-two of this form of cancer. He gave an account of these five cases, a study of which led him to agree with Pozzi that the symptom was rare, and probably neuralgic in character.

The PRESIDENT said that he was surprised to note Professor Miles Phillips's high percentage of pain. He had referred to his private cases, totalling thirty-four, and found that in twenty-four there was no complaint of pain at all. Two of these patients had dilation of the cervix with growth palpable at the external os, but without invasion of the cervix by malignancy. It would appear unlikely, therefore, that pain was associated with attempts at extrusion. Five of his patients had complained of gnawing or cramp-like pains without periodicity; four of these cases were operable. Five patients complained of pain arising apparently outside the uterus and referable to intestinal colic from adherent intestine, suppurative appendage disease, and prolapse.

A CLINICAL MEETING of the Harveian Society was held at the Royal Waterloo Hospital on February 16th at 5 p.m. The president, Dr. HERBERT FRANCH, took the chair. Seven cases were shown by members of the staff of the Royal Waterloo Hospital: and two cases by Dr. TURTLE and Dr. COVE-SMITH. The cases were fully discussed by the members and visitors, and at the conclusion of the meeting a cordial vote of thanks was passed to the staff of the Royal Waterloo Hospital.

## Rebicus.

### SOLLMANN'S PHARMACOLOGY.

SOLLMANN'S *Manual of Pharmacology*,<sup>1</sup> the third edition of which we have received, is well known as the largest textbook of pharmacology in the English language. The volume contains nearly 1,200 pages, and it is of particular value to advanced students because a full account is given of the chief recent research work in the subjects dealt with, and moreover an excellent selected bibliography of a hundred pages is included. This textbook is therefore one that has established a high reputation as a convenient and well-balanced work of reference. We are glad to say that the author has shown great industry in bringing the work up to date, and has included all the numerous new drugs of importance that have been introduced into medicine in the five years that have passed since the last edition appeared. He mentions in his preface that the recent advances made in pharmacology have necessitated the rewriting of many sections of the book, and that the bibliography has been extended by 1,200 new references.

The scope of the book may be indicated by a few examples. The pharmacology of lead occupies seventeen pages and contains references to the treatment of cancer by injection of colloidal lead, and also a page and a half on the toxic properties of tetra-ethyl lead. His conclusion on this last subject is, that although tetra-ethyl lead is a highly toxic substance, yet the danger to the public from its use in petrol appears to be slight, although decisive data are still scanty. Among the new substances mentioned for the first time are insulin, parathyroid extract, and the new chemo-therapeutic agents such as Bayer 205, and the various organic arsenicals. The author takes a wide view of his subject, and has included an account of vitamins and radiations and some discussion of other problems which lie on the borderline of pure pharmacology.

Dr. Sollmann's general outlook indicates a rational scepticism. This is illustrated in his summary of the results of glandular therapy. He points out the knowledge that it is essential to possess before any glandular preparation can be used with any certain success in therapeutics, and then concludes:

"Gland therapy can be established on a sound basis only in the direction that has been indicated, however difficult and laborious and tedious this may appear. Its development is rather hindered by premature enthusiasm which is inclined to dispense with definite criteria of action, with adequate controls, with effective preparations or efficient channels of administration, and often with critical diagnosis; which interprets psychic manifestations as scientific observations, and which depends on 'autistic judgement,' that is, judgement or rather credulity based on desires instead of facts."

This volume, as we have indicated, is, without doubt, the most extensive work of reference in pharmacology in our language. In former editions there was a tendency for the accounts of the details of conflicting evidence to obscure the main conclusions, but the new edition shows much improvement in this respect. The author states that the dominant object of the manual was to serve as a textbook for medical students, but it is scarcely suited for the routine use of undergraduate students in this country, because the time they devote to pharmacology is insufficient to allow them to master a work of this size.

### MIND GUIDANCE.

THE title of Dr. AVELING's book, *Directing Mental Energy*,<sup>2</sup> is sufficiently arresting to cause the student to stop and inquire whether here at last will be found a real attempt to explain the secrets of self-direction and of those phenomena which underlie the conversion of psychical "potential" into kinetic "drive" and accomplishment. The problem is a fascinating one, and should this work lead to the discovery of some tangible clue to the secrets

<sup>1</sup> *A Manual of Pharmacology*. By Torald Sollmann, M.D. Third edition, entirely reset. Philadelphia and London: W. B. Saunders Company. 1927. (Roy. 8vo, pp. 1184 35s. net.)

<sup>2</sup> *Directing Mental Energy*. By Francis Aveling, M.C., Ph.D., D.Sc. London: University of London Press, Ltd. 1927. (Demy 8vo, pp. x + 276; illustrated. 8s. 6d. net.)

of mental energy and its direction, we would indeed be under a heavy debt to the author.

We know, at any rate, that Dr. Aveling possesses the necessary qualifications for his task as guide. He is University Reader in Psychology at King's College, London, and president of the British Psychological Society, so it will not be due to any lack of scholarship if he fails us. Unhappily, he does fail us. We say this in spite of his caveat that the title of his book must not be misapprehended. We feel that Dr. Aveling has set out to write just such a work as many have searched for, a work in which all his erudition and experience would be focused upon the task of penetrating into the psychological foundations of mental energy, inquiring into its manifestations, and showing how it may be maintained and directed. "This book may be regarded," he says in his introduction, "as an attempt to present and solve in part a problem of great importance—the problem which in its widest aspect might be stated in the terms 'How much can be made out of life?'" Thus far, satisfactory. The reader's hopes are raised, and he pleasantly anticipates the answer to this all-important question. But no sooner does Dr. Aveling propound this question to himself and to his readers than he begins to whittle it down, and we are informed a little later that the problem thus stated offers apparently insuperable difficulties. And so he alters his plan. A few lines farther on he says: "We shall not be concerned here with making economies instead—little economies that living at all entails—economies in our physical and mental energy."

With this revised and somewhat attenuated thesis Dr. Aveling seeks to show the wastage that takes place in mental energy—wastage of human energy, bodily energy, and mental energy, will wastage and emotional wastage. When it comes to showing how and where to wield the economic axe in the interests of mental capital Dr. Aveling is thoroughly at home, and his suggestions are many and valuable. He gives a number of devices for economizing energy in remembering which should prove of real service to the student. The first of these principles of economical learning is that an attempt at actual recall after a little learning is far more serviceable than the mere continuance of repetition in learning itself. The second shows the advantage of learning by "spaced repetitions" rather than by continuous repetitions. The third concerns and advocates the learning of a passage as a whole rather than in parts.

The chapter on emotional wastage is of interest. Dr. Aveling's sovereign remedy here lies in the practice of relaxation; by bodily relaxation mental strain and tension are relieved. The question of will wastage presents more difficulty. There is no test of will as there is of intelligence; but Dr. Aveling has also suggestive things to say with regard to the problem of the education of the will, and several economies to propose. There are chapters on mental tests and on vocational guidance, and considerable space is allocated to the discussion of the problems regarding successful "sublimation."

This is a book which cannot be read without profit.

#### GASTRO-DUODENAL RADIOLOGY.

THESE large and important volumes, one on the radiology of the stomach, the other on the duodenum, the work of PIERRE DUVAL, J.-C. ROUX, and HENRI BÉCLÈRE, are two of a series of books which, when completed, will form "The Archives of Clinical Radiology." After describing and illustrating the normal, each pathological condition is taken up separately, and a short note suffices to introduce a series of radiograms showing the x-ray appearances which accompany the disease under discussion. These illustrations are in reality the great feature of both volumes, and are very numerous, some 400 altogether. The size of the pages is such that four radiograms—4½ inches by 3½ inches—can be put on one page. The arrangement is that when the book is opened these will

<sup>1</sup> *Radiologie Clinique du Tube Digestif: I. Estomac et Duodenum.* Par Pierre Duval, Jean-Charles Roux, Henri Béclère. Clinique Thérapeutique Chirurgicale de la Faculté de Médecine de Paris. Paris: Masson et Cie. 1927. (Double Roy. 8vo, pp. 333; 400 radiograms, 432 figures. 265 fr. the two volumes.)

appear on the right-hand side, and facing them on the other side are outline drawings of the same radiograms with short explanatory notes, and in some cases additional drawings are added to make the condition clearer. The authors state that they have been collecting the radiograms for a considerable number of years, and that, working with the collaboration of their medical and surgical colleagues, it may be assumed that all the cases are authentic, the diagnosis not having been made on the x-ray examination only.

Many so-called atlases of radiography have appeared in recent years consisting of a more or less heterogeneous collection of x-ray pictures, with a short description of each attached. These form excellent "picture books," but in no other respects do they fulfil any particularly valuable purpose. Whilst retaining some of the features of such an atlas—inasmuch as radiograms, and explanatory drawings and notes accompanying them, constitute the backbone of these French books—each of the volumes under review goes very much further. In the first place, the considerable letterpress which precedes each division of the subject describes very fully and in detail the various points in the pathology which cause the x-ray deviation from the normal, and discusses both the clinical and the radiological features. A further point is that each disease is represented not by just one radiogram, but by a series of reproductions showing the different appearances which can be caused by the same disease, varying very considerably in different cases according to the manner and position of attack, and the future development of any disease.

While saying so much in praise of these works we are bound to add that in one important respect they are open to severe criticism. Nearly all the radiographs are of poor technical quality, practically none comes up to that standard of excellence which modern apparatus and modern technique make possible, and not a few would be quite unintelligible except for the line drawings accompanying them. That it is the radiograms themselves that are at fault and not the method of reproduction is evidenced by the fact that the paper on which they are reproduced is of excellent quality and one side of it only is used. There is no doubt that this is a serious drawback to both volumes, and one which detracts considerably from their value. The best diagnostic work must always be backed up by the best technique, without which it of necessity fails to carry full conviction.

#### PRISON-BREAKERS.

THE increased and apparently still increasing popularity of what are known as detective stories is not the only sign at the present time of a love of tales of crime. It seems that fiction alone cannot satisfy the appetite of the public, for the number of publications dealing with actual crimes and criminal trials has also increased. Of necessity these latter are all at least twice told tales, and some of them have formed the subjects of popular novels such as Ainsworth's *Jack Sheppard* and *Rookwood*, which with other works of fiction called forth Thackeray's indignant counterblast of *Catherine*. In that book he strove to sweep away the false glamour with which his predecessors had invested vulgar ruffians, and in it he announced his intention "to take a few more pages from the 'Old Bailey Calendar,' to bless the public with one more draught from the Stone Jug:—yet awhile to listen, hurdle-mounted and riding down the Oxford Road, to the bland conversation of Jack Ketch, and to hang with him round the neck of his patient at the end of our and his history." Mr. PHILLIP, in his book *The Prison Breakers*,<sup>4</sup> makes no pretence to do more than amuse his readers by relating with gusto the stories of the escapes and attempts to escape of John Nevinson, Jack Sheppard, David Haggart, Louis Cartouche, Louis Napoleon, George Kelly, and Frederick Trenck.

The *Dictionary of National Biography* may tell us that the real Turpin was a mean and repulsive ruffian, who never rode to York on Black Bess or any other mount, but that disclosure only affords an opportunity of describ-

<sup>4</sup> *The Prison-Breakers.* By Alban M. Phillip. London: P. Allan and Co., Ltd. 1927. (Cled. 8vo, pp. x + 262; 8 plates. 10s. 6d. net.)

ing the feats of John Nevinnson, who, it seems, really did establish an alibi by riding from Gadshill, near Strood, in Kent, to York in fifteen hours. In spite of its title Mr. Phillip's book includes in most cases a description of the offences that preceded and generally followed the escapes of his heroes. There are exceptions to this statement. Baron Trenck and Louis Napoleon were not criminals in the ordinary sense of the word: the former was not condemned by any process of law, and the latter was sentenced for a political offence and treated with a leniency which was to have tragic results for France and for Europe twenty-four years later. George Kelly, also was a political prisoner, whose walking out of the Tower of London by the public gateway can no more be described as prison-breaking than the escape of Louis Napoleon, although a nice sense of honour might stigmatize Kelly's action as parole-breaking.

Uniform with *The Prison-Breakers* is the volume by Mr. PHILIP MURRAY, wherein are described *The Strange Adventures of Frederick Baron Trenck*.<sup>5</sup> It appears that we have only his own word for the greater part of the truly surprising story of this Prussian Baron Trenck (he had a cousin in the Austrian service), and since some of his statements are incredible, we are inclined to agree with Carlyle, who denounced him as a liar and a ruffian, or at least to accept none of his more startling stories without independent corroboration. Again and again in reading this book we have been irresistibly reminded of two frankly fictitious autobiographies—those of Mr. Barry Lyndon and Major Gahagan. Surely Thackeray was well acquainted with Trenck's book! If Trenck's achievements are not quite as startling as those of his countryman and contemporary Baron Münchhausen, they are surprising enough. No prison walls, iron fetters, nor high-born ladies' hearts could withstand his attack, and he boasts with an almost brutal frankness alike of the favours as of the hard cash which he received from his noble or princely mistresses.

### THE FUTURE OF MARRIAGE.

THE pamphlets of the "To-day and To-morrow" Series follow each other so rapidly that "To-day" may soon be passed, and we shall be educated up to the standard of "To-morrow." Although differing widely in their subject matter all the books that have appeared have two attributes in common—they are readable and they make the reader think. *Hymen: or the Future of Marriage*,<sup>6</sup> by Dr. NORMAN HAIRE, is no exception. The author frankly anticipates that some of his opinions will appear startling to readers unacquainted with sociology. They will only startle those who have unquestioningly accepted conventional standards and have never tried to examine the problems of life with complete scientific objectivity. As regards sexual functions the author prophesies increased freedom for the individual, in certain directions, so long as his activity does not harm the community; in others he thinks there will be more safeguarding of communal interests. He gives many examples to show how the meaning of morality differs in different countries. In answer to those who have so little faith in human nature as to imagine that if legal and religious prohibitions were withdrawn almost all men and women would at once fly to excess, the author declares that among the married and the unmarried sexual excess is far less common than sexual starvation. In his view excess is more often than not the direct reaction to and result of an antecedent starvation.

Many subjects usually regarded as controversial are touched upon, and the author suggests some of the lines upon which the thought of the future may proceed. On such matters as sex education of children, prostitution, contraception, marriage, divorce, venereal disease, and sterilization of the unfit his remarks are carefully rea-

soned. The objective attitude is maintained throughout. He believes that "life-long monogamous marriage is the ideal to aim at," and also "in the age to which I look forward the parent will be ambitious to leave his child not a large store of worldly wealth, but a good heredity, physical and mental." In conclusion Dr. Haire says, "I aim only to stimulate people to think for themselves, and to endeavour to arrive at rational standards of their own, based, not on superstition, but on the fullest knowledge that they can obtain."

### NOTES ON BOOKS.

THE output of books on child psychology is prodigious. Some of them are undoubtedly useful, and in this group we would place *Everyday Problems of the Everyday Child*,<sup>7</sup> by Dr. DOUGLAS A. THOM, director of the Habit Clinics of Boston, Massachusetts. It is an eminently readable book, designed for parents, teachers, and nurses; plainly and simply written, without technical and sometimes incomprehensible terminology; clean and wholesome, without mawkishness. The problem of the child—at least of the child who is not the perfectly happy, careless, and delightful child—is by no means easy, not nearly so easy as writing about it would make it seem to be. "This kind goeth not out without much prayer and fasting" on the part of parent or teacher. Yet it is good to hear of what successes others have had with difficult children.

How far does the catchword "a human document," printed on the jacket of a new book, encourage its perusal? To the reviewer it is suggestive of boredom and egotism. *The Locomotive-God*,<sup>8</sup> by Mr. LEONARD, does not belie the suggestion. The author is an American, described as a poet and a scholar. He has known many eminent persons, and he tells us that Arthur Symonds and Edward Dowden welcomed him as an authentic new poet in their common tongue. Unfortunately he has suffered all his life from "terrific psychological abnormalities," and his chief phobia is a constant dread of noise and turmoil. With wearisome industry he has searched his mind for memories of his child life, and has succeeded in getting back to the early age of 2 years 4 months and 10 days, when he stood for the first time on a railway platform. A train approached, and in the black circle of the front of the locomotive he saw the face of God. As he turned to fly, steam from the piston-box added to the child's terror by penetrating his anus. On the basis of this recollection, told in great detail, the author explains his unhappy life, and he finds in the locomotive god, which gives its name to his 420 pages, an explanation of his phobias. He is at pains to explain, perhaps not very convincingly, that his family was entirely free from neurosis; but even if the engine provided the exciting cause, or at all events the colouring material, of his psychological abnormality, the predisposing condition for so unusual an occurrence must have existed in his own mind. Failing a locomotive god an aeroplane, or perhaps a jazz band, might have had the same effect. Mr. Leonard has investigated himself by self-analysis, and by means of hallucinations in what he calls "twilight sleep," and in crystal gazing. It is possible that connoisseurs of the commonplace may be able to extract some crumb of interest from this lengthy record, but it may be doubted whether the investigation has been good for Mr. Leonard, or is of any particular value to the general reader, medical or otherwise.

Since 1924 there has been a steady fall in the number of names added annually to the *Medical Register*,<sup>9</sup> and the issue for 1928 contains 1,941 new registrations compared with 2,120 for the previous year. The membership of the medical profession continues to grow, and for 1927 the total is 53,769, an increase of 1,155 on the figure for 1926. The effects of the exceptional circumstances created by the war are reflected in the fact that the average number of new entries for the past five years has been 2,377, while the average for the last twenty years was 1,577. New registrations in England during 1927 numbered 971, in Scotland 462, in Ireland 274, in the colonies and abroad 234. Registrations in Scotland show a remarkable decline from the peak of the post-war summit in 1924, when the number was 935, or more than double last year's total. In other areas the change has been less pronounced. The number of names removed from the *Register* in 1927 was 1,035, as compared with 1,159 in 1926. Last year 840 names were removed on evidence of death, 2 on ceasing to practise, 191 because of failure to reply to the inquiries of the Registrar

The makers explain that their vitamin D preparation (radiostol) has given very favourable results in the treatment of rickets, and that they have prepared this new preparation because there is considerable evidence in favour of the view that vitamin A is an important factor in the maintenance of resistance to infections. They have been able to prepare a vitamin A concentrate from a newly discovered source of this vitamin, and are putting forward the combination of the two vitamins for clinical trial.

In the small hours of Sunday morning the prince was seen by Gibbons. The same day the Princess Anne was persuaded to summon the famous John Radcliffe to a consultation. Although Radcliffe was credited with having saved the life of the prince when 3 years old, he had since forfeited Anne's good favour, "by his too great Addition to the Bottle," says Pittis. According to this writer and others, a violent altercation broke out between Radcliffe and his brother practitioners; from our knowledge of

Radcliffe this seems likely enough, but the story that he refused to prescribe for the patient, and declared he would die the following day, is clearly unfounded.

Gibbons records that when he first saw the prince on Sunday

"betwixt Three and Four in the Morning." "He swallowed with ease, and when I looked into his Throat I found nothing amiss there. About Eight the same Morning . . . Eruptions began to appear in his skin, which towards the Afternoon increas'd, and at Night appear'd like a Rash." He confirms the diarrhoeal symptoms, and mentions vomiting of "Vesci'd Phlegm." "He continued in a breathing Sweat and the Rash out, till about Eleven of the Clock last Night [that is, Monday] when on a sudden He was seiz'd with a difficult Breathing, and could swallow nothing down, and dy'd before Midnight."

Radcliffe made his examination of the prince at six on Sunday evening, when

"I found his Highness in bed with a very high Fever upon him, his Flesh extream hot, and a high colour in his Cheeks, with several Eruptions upon his Skin and Face, attended with a Rash; which gave some Suspicion that it might prove the Small-Pox: His Pulse was very quick and Feverish; His Tongue White, and his swallowing without pain or difficulty; his Breathing by fits short and attended with great sighing."

He too mentions the diarrhoea, and gives details of his treatment, thus disposing of the story that he refused to prescribe.

On Monday morning, "He was less Light-headed, and the Rash came out more, so that towards Noon his Head was considerably better, and his breathing freer, which gave us some Encouragement at that time to hope his Recovery." But, "He was on a sudden, after a little dosing, taken with a sort of Convulsive Breathing with a defect in Swallowing, and a total Deprivation of all Sense, which lasted about an hour, and so between Twelve and One at Night he departed this Life."

Seemingly there were two elements in the exanthem—one more diffuse, the "rash" which appeared on Saturday (third day), and a more discrete "eruption" which showed itself on the morning of Sunday (fourth day). If the latter was a true small-pox rash it would not have assumed a definitely diagnostic appearance at the time of death. Clearly Radcliffe thought that the eruption had not sufficiently matured to warrant a definite opinion, and except for his suggestion of small-pox, contents himself with calling the malady "A Malignant Fever with a Rash attending it." Bishop Burnet borrows Radcliffe's term "malignant fever"; while Evelyn makes the unqualified assertion that the prince "died of the small-pox."

The foregoing clinical reports of Hannes, Gibbons, and Radcliffe I have extracted from their letters, dated July 30th, given in a most interesting but little-known tract in the British Museum, and I am convinced of their authenticity. There is no reference to this tract or its contents in any account of the prince's illness which I have seen. It is clear that Hannes's letter is the unacknowledged source of Bishop Kennett's description in his *History*, where it appears, in great part word for word. Sandford reproduces it with equal faithfulness in his narrative of the prince's death and burial. James Johnstone, writing in 1779, quotes a condensed version of Bishop Kennett. Miss Strickland's account is too fanciful and inaccurate to repay inquiry into its origins.

The further evidence, which I have mentioned, appears to have escaped the notice of medical commentators; certainly, like the tract just cited, it was unknown to that tireless scholar the late Dr. Creighton, and this alone would be sufficient justification for calling attention to it here. I refer to the report on the *post-mortem* examination, which is entitled:

*An Account of the Dissection of his Highness William Duke of Gloucester. Drawn up by Doctor H. and Sign'd by Him, and by the Surgeons. From the Original Letter that was sent over to his Majesty in Holland.*

The preamble states that the examination was made, in the presence of witnesses, by order of the Earl of Marlborough, one of the Lords Justices, "and Governour to His late Highness." Unfortunately nothing is said of the rashes, presumably because their presence and characters had not been in dispute during life. Except for the signi-

ficant extract which follows in full, the report merely records changes indicative of some acute toxic state.

"4. The Neck was Swoll'n: And upon Dissection the inclosed Parts appear'd such, as they are observed in Bodies strangled.

"At the place where the Jugulars arise above the Claviculae, the Inflammation approach'd very near to a Mortification.

"The Glandulae Thyreoidae were almost black with the contain'd Blood: and being put into Scales were found above Five Drachms in weight.

"The Gullet was much Inflamed; the Windpipe also was affected in the same kind, especially the upper part of it call'd the Larynx. In the Larynx the Membranes that join the Cartilages Cricoides and Thyreoides were very dark with the Inflammation.

"The Membrane that lines the Epiglottis (at the root of the Tongue) was also Inflamed: insomuch that the Glandulae Miliares of it, which are scarce visible at other times, were here much distended and very conspicuous.

"5. In the Mouth, we found the Palate inflamed; as also the Uvula, the Membrane of which was swell'd.

"The Almonds of the Ear (in the Throat) [Tonsils] were swell'd; and had in them Purulent matter: there being press'd out of one of 'em as much Corruption, as fill'd a Tea-spoon."

The report, dated July 31st, is signed by Hannes and three surgeons.

The immediate cause of death was an acute phlegmon of the throat, but whether primary, which the rather gradual onset suggests, or secondary to one of the acute fevers, is difficult to decide if we keep strictly to the facts as we have them. The absence of difficulty in swallowing is striking. The report gives no hint of any membrane, and this, if present, could scarcely have escaped notice; nor does the condition described suggest a complication of small-pox at the fifth day. In some ways the attack resembles scarlet fever, but the late appearance of the rash is out of keeping. Measles, too, is a possibility, but there is no mention of any catarrhal symptoms, the importance of which was recognized in that age. If the symptoms had suggested either of these eruptive fevers, presumably it would have been diagnosed, but the only diseases considered in the reports are small-pox and the vague "malignant fever," a term which even then had no specific meaning. In my opinion the malady may well have been small-pox complicated by acute laryngitis, the tonsillar condition possibly being pre-existent.

Later, the three surgeons who had performed the autopsy issued the following signed "Certificate":

"Whereas 'tis reported that we the Surgeons, who Dissected the Body of his Highness the Duke of Gloucester have given it as our Opinions, that He dy'd of a Quinsy, or sore Throat: We do now (as we did upon Dissection declare our Opinions) that the sole Occasion of His Highness's Death was a very high Malignant Fever."

The physicians were much abused for their supposed mismanagement of the case, but it does not appear that any treatment then possible could have averted the fatal issue. Queen Anne gave no evidence of subsequent mistrust in Hannes, for he was appointed her own physician two years later, and knighted by her in 1705. A satirical poem entitled "Doctor Hannes Dissected" ridicules him for his failure to arrive at a final diagnosis either during the prince's life or after his death:

"But how so great a man of Art,  
Should let a Royal Hair Depart,  
And never tell the reason why,  
He shou'd not Live, or he shou'd Dye!"

W. P. MACARTHUR.

## TOXICOLOGY IN RELATION TO MEDICAL PRACTICE.

HARVEIAN LECTURE BY SIR WILLIAM WILCOX.

At a meeting of the Harveian Society of London, held at Paddington Town Hall on March 15th, under the presidency of Dr. HERBERT FRENCH, the fifty-fourth Harveian Lecture was delivered by Sir WILLIAM WILCOX, whose subject was toxicology in its application to medical practice.

Sir William Wilcox remarked that in modern times toxicology had risen to a position of the utmost importance in the profession; indeed, it now formed an integral and inseparable part of medicine. In recent years the theory of focal infection as an important factor in the causation of many pathological conditions—such as chronic rheumatism, gastric and duodenal ulcers, and diabetes, and as exemplified in the contribution of tooth sepsis to bodily disease—gave an extended field to this department. Little was known as yet of the nature of the poisons which caused such conditions as uraemia and eclampsia. The blood-urea test was of great value, but it was not the urea in the blood which caused the toxæmia; it was something the composition of which had not yet been determined. Toxicological researches on these lines would do much to advance knowledge regarding the causation, and therefore the prevention and cure, of disease.

Pharmacology was closely related to toxicology; the therapeutic action of a drug easily merged into a toxic action. Idiosyncrasy and variations in the degree of tolerance to a drug were constantly being encountered, these being probably often due to defective function of the liver or other organs. With regard to the rashes following on the administration of bromides and iodides, he spoke of a case in which a large lump developed on the face, and the diagnoses advanced included sarcoma. Then it became known that the patient had been taking iodide, and this knowledge saved an operation, for on stopping the iodide the lesion subsided. An eruption might follow quite small doses of this drug in some people, even as little as 3 grains three times a day for bronchitis. Accompanying the iodide there was often a salty taste in the mouth, and an irritating catarrh of the nasopharynx.

### *Toxic Effects of Therapeutic Doses.*

Even in therapeutic doses belladonna preparations might cause dryness of the mouth, impairment of vision due to paralysis of the pupil, as well as difficulty in passing urine, perhaps because of the action of the drug on the nervous system. A dose of 1/100 grain of atropine would cause retention of urine. Salicylates and salicylic acid preparations might cause deafness or vertigo, and, in those susceptible to salicylates, cardiac disturbance such as faintness and tachycardia. Large doses of the drug might give rise to the symptoms of acidosis, and then acetone and diacetic acid would be found in the urine. The doctor should be on the watch for this when employing salicylates; it was well to give in addition bicarbonate or citrate of sodium.

Mercurial preparations when used extensively, as in the treatment of syphilis, might cause offensive breath, furred tongue, salivation, stomatitis, looseness of teeth, diarrhoea, even ulcerative colitis. These symptoms were rarely seen nowadays, however, owing to the use of alternative preparations for this disease. When epidemic jaundice was so common during the war there were many cases of mercurial stomatitis. The administration of opium preparations required much care, especially in the young, and in adults with renal and hepatic disease. He had seen a small dose of heroin, given to procure sleep, cause suppression of urine. Quinine might cause headache, deafness, noises in the ear, and vertigo, but these could be controlled by giving bromides. In persons having a special idiosyn-

crasy towards quinine the drug seemed to have a selective action on the retina, and partial blindness might follow a quite small dose; even optic atrophy had been known to follow. With the use of quinine for malaria in the Salonica campaign there were many cases of optic atrophy. With regard to modern pharmacology, large doses of powerful drugs were at the present day advocated for treating a number of diseases. Atoxyl had been used some time before its affinity for the optic nerve was generally recognized; this danger had not been pointed out by the vendors of the drug. After salvarsan nausea, slight albuminuria, and a small rise of temperature lasting twenty-four hours generally occurred. Therefore, there must be no happy-go-lucky way of administering these remedies. Arsenobenzol might have a bad effect on the liver, and jaundice might result from the hepatitis following its use, this manifestation sometimes being deferred for a few weeks. Ehrlich took extraordinary precautions regarding salvarsan before he issued it for general employment, and, what was very important, each packet set out the dangers and the contraindications. Preparations of bismuth for intramuscular use in syphilis were not free from toxic effects either; he had seen cases in which convulsions and coma followed their use. Trypanosomiasis and kala-azar called for powerful remedies, and care was required in their administration to avoid toxic effects.

The treatment of cancer by lead, recently introduced by Dr. Blair Bell, was an example of the careful use of a poisonous metal to produce the best effect without causing

The treatment consisted of intravenous lead 5 per cent. until, over a period of 10 days, the patient had received a total of 0.5 of a gram. This had thrown a good deal of light on the toxicology of this metal; lead introduced intravenously did not produce the symptoms from which the plumber suffered. In the case of most poisons the great burden was borne by the liver, though other organs shared too, and jaundice was not always present.

### *Dangers of New Remedies.*

The quinolin group had been found to act as liver poisons, and in some cases caused fatal toxic jaundice. From such drugs as these there might occur mental irritability, vomiting, twitchings, stupor, coma, convulsions, and death, the temperature becoming very high just before the end. The cumulative effect of such drugs must always be remembered. He had known acute yellow atrophy, with a fatal termination, occur ten years after employment in a munitions factory in association with tetranitrotoluene.

An interesting and important point was that of adopting measures to prevent or minimize liver poisoning. It was found that if the liver cells were stored with glycogen they were able to stand more damage than otherwise; it was well known that alcohol had much less effect when taken on a full stomach than when fasting. Therefore, three hours before the injection of any drug, 40 grams of glucose in coffee should be given.

Recently many new drugs, a large proportion of them of foreign manufacture, had been placed on the market, and their virtues were highly extolled by the manufacturers and the vendors. Attention was rarely called, however, to the toxic and other harmful effects which were liable to follow their use. He thought it most unfortunate that the makers of drugs did not more fully take the medical profession into their confidence. Certainly the medical practitioner would feel more confidence in a new drug brought to his notice if all the possible sources of danger were carefully indicated. No fewer than 257 cases of fatal poisoning with the barbituric group had occurred in the last twenty years.

Pharmacology was changing; the bottle of medicine was giving place to the animal extracts. Insulin was a very toxic drug, and great care was needed in its use; pituitary extract might cause rupture of the uterus if incorrectly used, and might also exert a powerful influence on the heart; adrenaline might cause cardiac collapse if the myocardium was weak. Care must also be exercised in the use of vaccines or antigens; the danger of anaphylaxis must be kept in mind.

*The Law and Poisoning.*

There was no legal definition of poison, but sections relating to criminal poisoning referred to a poison or other destructive or noxious thing. In abortion cases "noxious thing" was used to mean something which might reasonably cause abortion. For example, 2 grains of aloes three times a day, or 10-grain doses of quinine, were regarded as noxious things. If a medical practitioner suspected that poison was being unlawfully administered to his patient he must make sure of his ground by having an analysis made by an experienced man, and meanwhile move the patient to a nursing home and place him in charge of a responsible nurse. He should also call in, at the earliest opportunity, another doctor in whom he had confidence. The poison laws were a wonderful protection to the public, and valuable information was obtained from the poison registers. A committee was now sitting to frame laws to include all the recently discovered poisons. Drug addiction had become a matter of international importance.

Sir William Willcox then made brief reference to commercial poisoning. The present great use of petrol had led to a number of cases of carbon monoxide poisoning; policemen on traffic duty had collapsed through inhaling petrol fumes. Tetra-ethyl lead was a very toxic substance, and showed a strong affinity for the nervous system. The full symptoms did not appear for months, and when in full measure they were probably incurable. A special committee had been appointed to investigate this question too, but it would probably have been better if this step had been taken before allowing the substance to be used. With regard to the treatment of poisoning in general, the first step was to remove the poison without delay—the stomach must be washed out. Then stimulant treatment should be adopted. Recovery might be a slow process.

On the motion of Dr. WILLIAM HILL, supported by the PRESIDENT, Sir William Willcox was cordially thanked for his lecture.

## VORONOFF'S EXPERIMENTS ON THE IMPROVEMENT OF LIVESTOCK.

LAST November a delegation representing the Ministry of Agriculture, and consisting of a physiologist, a geneticist, a dietician, and a veterinary surgeon, visited Algiers, where, in company with similar delegations from other countries, Dr. Serge Voronoff demonstrated testis grafting in relation to agriculture. The delegation had three main aims: to study the technique, to examine animals subjected to this technique, and to investigate the economic results.

The technique, which is described in full detail in an appendix to the report of the British delegation,<sup>1</sup> consists essentially in the implantation of pieces of testicular tissue from one male on the surface of the testes of another. For the human subject monkeys and apes act as the donors, but in animals it is possible to use a male of the same species. The scrotum is opened, the surface of the testes is scarified to provoke a mild aseptic inflammation, and on this scarified area pieces of freshly excised testis are implanted and stitched in position. If the operation is performed properly untoward sequels are rare.

It is claimed that the new testicular material replaces or reinforces the physiological action of the animal's own testis, and so restores or increases the degree of manifestation of those characters which depend for their expression and full maintenance on the proper functioning of the gland. It is claimed by Dr. Voronoff that these glands also play an important part in the maintenance of general vigour. He has employed this operation on animals for two distinct purposes: to rejuvenate and restore the reproductive powers of decrepit and infecund males, and to stimulate the growth and general vigour of sexually immature males, whose testes have not yet profoundly affected the developing characterization of the individual.

The delegation examined a bull (Jacky) discarded as useless in 1922, when 17 years of age, and operated on in 1924 by Dr. Voronoff. During the next two years Jacky sired nine calves, after which his reproductive powers seemed to wane, and the operation was repeated, apparently with some success.

The delegation points out, however, that it is difficult to accept this case as a complete and unqualified substantiation of Dr. Voronoff's claims concerning rejuvenation. Stud bulls are usually discarded in Algeria when about 12 years old, and the fact that Jacky was retained in use so long suggests that he was an exceptional animal and that he may have reacted more strongly in consequence. He cannot be compared with bulls in Britain, which are generally discarded when 4 to 5 years old, and exact data as to the age to which a bull may prolong his sexual vigour are not available. Jacky, moreover, may have been in ill health prior to the operation. In any case his subsequent fertility ratio was exceptionally low, and there is a vague suggestion of doubt as to the paternity of some of his calves. The delegation believes that, although this example may support Dr. Voronoff's first claim, it cannot be accepted as conclusive proof. In any case the use of this procedure in British stock breeding would be slight and confined only to very special sires; alternative methods, such as improved management, are available for extending or increasing the usefulness of such animals. It is recommended, however, in the report that further experiments in this direction should be encouraged owing to the possible value of the method in sire-importing countries.

In connexion with the second purpose of the delegation a number of flocks were inspected in which the operation was claimed to increase the production of both mutton and wool. Here, however, the evidence was less satisfactory, the exhibit being rather in the nature of a sample of an established fact. Definite and detailed information concerning the numbers involved, or of the pedigree and relationship of the individuals exhibited, was not forthcoming. Moreover, the sheep were not confined under proper experimental conditions, nutritional factors were disregarded, and control was unsatisfactory. In the matter of weight of progeny, among the samples submitted grafted rams were superior to the non-grafted. Whether this was due to the direct action of the sexual hormone or to an increased rate of growth which might have been conducive to an improvement of type could not be determined. The fleeces varied very much in weight, and although it was claimed that there was an increase in weight of wool, samples showed no improvement in quality.

The delegation considers that the increment of both weight and fleece attained by the grafted sires can have no value in comparison with the cost of the operation, ram flesh being inferior in quality; it is only in the transmission of desirable characteristics to the progeny that its value might lie.

The economic advantages of this procedure in Britain are thought to be doubtful; it is desirable here to increase the quality rather than the quantity of wool. There is no demand for larger carcasses, but the more rapid attainment of weight for age might be an economic advantage, provided this is considered in relation to cost of upkeep.

The British delegation concludes that the claim to effect rejuvenation of the aged and decrepit male may be justified, although the evidence is not based on critical experimentation. In any case its value in a sire-raising country like this is doubtful, its usefulness being limited to sire-importing countries. The second claim of increase in body weight and wool clip is supported by the figures submitted and the sheep exhibited, but the conditions under which the experiments were conducted, the inadequacy of the data, and the methods of presenting them prevent the formation of a critical opinion. Its direct economic advantages appear to be negligible. Dr. Voronoff's further claim that these "improved" characteristics are inherited involves the acceptance of the hypothesis of the inheritance of acquired characteristics, which has never been substantiated. It is suggested, however, that both claims might be tested further and more critically in this country, where conditions are more favourable to scientific control than in Algeria.

## THE HASTINGS POPULAR LECTURE.

## THE FOUNDATIONS OF HEALTH.

LECTURE BY SIR GEORGE NEWMAN.

THE second popular lecture instituted by the British Medical Association, and associated with the name of its founder, was delivered in the Great Hall of the Association's House in London on Wednesday evening, March 21st. The lecturer was Sir GEORGE NEWMAN, K.C.B., Chief Medical Officer to the Ministry of Health and the Board of Education, and the chair was taken by Lord COZENS-HARDY. Among those on the platform were Sir Ewen Maclean (President-Elect of the Association), Dr. C. O. Hawthorne (Chairman of the Representative Body), Mr. Bishop Harman (Treasurer) and Mrs. Harman, Dr. Arnold Lyndon, and Dr. E. Lewys-Lloyd, Dr. Christine Murrell, and Mr. E. B. Turner (members of Council), Dr. E. Graham Little, M.P., and Mr. C. G. Ammon, M.P. A wet evening militated against as large an attendance as that at the first lecture by Sir Berkeley Moynihan a year ago, but the body of the hall was well filled.

Lord COZENS-HARDY, in opening the proceedings, said: I can imagine no subject of greater importance to the nation than that which has been chosen for the lecture of to-night, and no man more fitted to deal with it than Sir George Newman. He is in a unique position for studying the problems of national health as a whole, and we have learned to expect from him definite guidance along a path mapped out by his knowledge and his vision. Progress along that path is slow, and yet how much ground has been covered since Sir Charles Hastings founded the British Medical Association! And the further we proceed along that path the quicker the pace tends to become. The comparatively recent formation of the Ministry of Health was a very great step in advance, and with a consistent policy at headquarters many obstacles to progress have disappeared. In local administration, however, we are still left with much overlapping and waste of effort. That is a state of affairs which will not be tackled by any Government until the nation at large has come to realize how uneconomic and unsatisfactory it is, and has become better educated as to health requirements and the best way of securing them. Sir George Newman has told us elsewhere that it is still too long before a fully substantiated medical truth percolates through the whole community, and I do not think he lays upon the public the whole of the responsibility for that delay. In these days, when increased interest in health matters causes every claim for advance in medical knowledge to be regarded by the press as good "copy," and by the advertising expert as a peg on which to hang a slogan, it is becoming increasingly difficult for the layman to determine when the point has arrived at which a reputed discovery has really become a substantiated medical truth, and authoritative guidance on these matters was never more needed than now. No one has done more to educate the public in this respect than Sir George Newman. In those able memorandums which issue from the Ministry of Health he has shown a great gift for putting his views on subjects which might be regarded as dry and uninteresting into a form calculated not only to interest but to inspire the layman and the medical man alike.

Sir GEORGE NEWMAN, before proceeding with his lecture, said: I appreciate very much the honour which the British Medical Association has done me in inviting me to deliver this lecture, but it is an honour which carries with it some embarrassment to myself, for I am called upon to follow in the footsteps of the first lecturer, my distinguished friend, Sir Berkeley Moynihan. Though my scope of subject is much wider than that taken last year by Sir Berkeley Moynihan, I have to confess to you that I am much less the master of my craft than he of his. Moreover, Sir Berkeley Moynihan is perhaps the greatest medical orator that we have now in England, and to attempt to follow him brings its own embarrassment. Lord Cozens-Hardy has hinted at another difficulty which I have. I am invited to address you for half an hour or so upon a subject on which you are addressed

every day of the week. No one of us ever takes up a newspaper without being advised as to the conduct in health matters of our personal lives. On Monday we are told that we must eat only brown bread; on Tuesday we are assured that white bread is equally good; on Wednesday that neither brown nor white bread is essential to life or health; on Thursday we are encouraged to believe that we must give up our ham and egg for breakfast and take only four tablespoonfuls of orange juice; on Friday we are told that we must wear warm clothing; and on the sixth day that the less we wear the better. There is rest on the seventh day, during which we are able to observe that the young women of the new generation are disposed to disregard all these recommendations except the last! In a predicament of this kind, what is a civil servant to do? He is accustomed to complete obscurity. His business is to pursue a hidden path and live a concealed life. But he is brought out of his obscurity into this rather uncomfortable prominence to offer his opinion upon this much discussed and thorny subject. I propose not only to be brief but to be plain.

Sir George Newman then proceeded with the lecture, which is printed in this week's *Supplement*. For lack of time he omitted certain portions, saying that those interested would be able to read the published version. The lecture was delivered with great vigour, and was loudly applauded at the close.

Sir EWEN MACLEAN moved a vote of thanks to the lecturer. Sir George Newman, he said, had claimed to be something in the nature of a concealed personality. That was not the way he impressed his fellow-students in the old days when the speaker was a student with him in Edinburgh, and he did not think it was true of his after-career. If the great progenitor of the Association could have cast his vision forward nearly a century to the setting of that occasion, and have heard the lecture by the man of the occasion, he would have seen of the travail of his soul and have been satisfied. The setting reminded them of the extraordinary developments of the British Medical Association. Some people who did not know what the Association was and did were apt to be surprised that it took an interest in the prevention of disease, because that course, pursued to the full, might be expected to have a detrimental effect upon the doctor's living, though, to be sure, whatever was done in the way of prevention, there would still be enough diseases to live upon, and to die from. But the Association was deeply interested, not only in the conditions of service and emoluments of the medical profession, but in research in all branches of medical art and craft with a view to the discovery of new truth and the elimination of old disease. The Ministry of Health itself represented a great achievement in preventive medicine, and the medical profession was fortunate that at the head of the medical staff of the Ministry there should be a man who interpreted his duties in no narrow or merely official spirit, but maintained the friendliest contacts with members of the profession and all concerned with communal health.

Mr. C. G. AMMON, M.P., in seconding, said that he noticed that Sir George Newman began his historical review at a time when this country was feeling the effects of the industrial revolution. He believed that at this moment the country was passing through another industrial revolution, based this time not on steam, but on electricity and chemistry, and that if the social chaos which followed the earlier revolution was not to be repeated the guidance and advice of people like Sir George Newman would be very necessary. Sir George had spoken of himself as a concealed personality, but in fact he had a flair for publicity which would make a politician green with envy, and he had, as no other man, made people appreciate the relation of personal conduct to personal health.

Sir GEORGE NEWMAN, after the vote had been passed with hearty applause, said he was very much comforted with the thought that on the morrow he would return to his life of obscurity, where, however, he would still remain their most obedient and grateful servant.

The proceedings closed with a vote of thanks to the Chairman, which the Rev. R. R. HYDE (director, Industrial Welfare Society) proposed, and Dr. E. LEWYS-LOYD seconded.

# British Medical Journal.

SATURDAY, MARCH 24TH, 1928.

## THE PILLARS OF HEALTH.

HEALTH has in all ages been more or less a matter of public concern. We know that with the ancient Greeks physical efficiency was a cult. In modern times, as the functions of government grew in scope and diversity, and protection from external or internal foes became subsidiary to the pursuit of the happiness and well-being of the governed, health as a means of happiness has come to be recognized as of paramount importance. The mediaeval ascetic ideal, which found extreme and grotesque expression in solitary posturing on a pillar in a state of semi-starvation, has now been replaced by a hygienic ideal embracing both the individual and the community. It is appropriate, therefore, that Sir George Newman, as Chief Medical Officer to the Ministry of Health and to the Board of Education, should choose "The foundations of national health" as the title of the second Hastings Popular Lecture, which he delivered in the Great Hall of the British Medical Association's House on March 21st. The full text of his address will be found in the *Supplement* this week.

There appears to be something rather significant about the number six in this connexion. Not only does Sir George Newman find that since the eighteenth century there have been six epoch-making advances in medical science; he finds also that the principles or elements of nutritional health for the body are six in number: food, fresh air and sunlight, exercise, warmth, cleanliness, and rest. The fundamental problem of health, he insists, is the wise and scientific nurture of the body, and therefore the construction of these six pillars of health must be based on knowledge. Organization of this knowledge, so as to provide opportunity for all men to ensure for themselves and their families the essential conditions of nurture, is for him a function of the State. "In a civilized State," he affirms, "it is the nature and nurture of the individual and the communal organization of opportunity which are the foundations of national health." Developing this idea to its logical conclusion, Sir George Newman summarizes the elements of the modern programme of hygiene under the headings of sanitary environment, systematic nurture beginning before birth, preventive organization, and public medical services. So closely are they interlocked that no local authority can afford to neglect any one of them.

A perusal of the Government activities included under each of these articles or elements of Preventive Medicine cannot but impress the reader with the enormous extent of the field of State health services to-day; and when it is remembered that the medical profession has been largely responsible for the origin and organization of all these services, it must surely be realized how near the doctor has come to supplanting the priest as the power behind the throne. But Sir George Newman wisely reminded his audience that, while sanitary and medical experts have their place, health is every man's duty, and that "progress

depends more upon social and moral evolution than the advance of sanitary science, more upon wisdom than knowledge." Therefore, while attributing in large measure the vastly improved health of the people of our generation to the fuller application of medicine and sanitation to everyday life, he generously acknowledges the even greater influence of the forces of education, sociology, and biology.

The pillar of health into the construction of which the Hastings Lecturer goes most fully is food. Here he treads, as he is well aware, on difficult and debatable ground, since the medical profession is by no means in a position to lay down dietetic rules that are applicable to all persons. The question constantly recurs to the mind: What is it that makes one man able to thrive, say, on a diet of nuts; and why should another object to drawing his vitamins from oranges and tomatoes, and yet continue healthy? It is even a matter for speculation how far any of Sir George Newman's well-thought-out food rules are universally valid, and to what extent their terms are definable. "Strict and persistent moderation" is a very variable quantity. Large numbers of people appear healthy, feel well, and do good work on what to others would be imperfectly masticated food, or food greatly in excess of physiological needs. Individual idiosyncrasy must have some bearing on the number of meals taken, on how much is consumed at each, and also on what is eaten and drunk. If we are perhaps less alarmed than we ought to be by the Lecturer's caustic commentary on the British workman's daily fare—"a tale of ham and beef, of beer and bread, of tea and pickles, of tinned meat and proprietary foods, or a weary round of bacon, herring, and cheese"—we can at least agree with him that the customary diet of the great mass of our people is far from perfect, and that, whatever else is left undone, something could and should be done to make their food more appetizing, and therefore more nutritious. Perhaps Sir George Newman, in his capacity of Chief Medical Officer to the Board of Education, may be able some day to induce local authorities to pay more attention to cookery in the curriculum of primary education: In dietetics balance is all-important. Every factor has to be taken into consideration—calories, a due proportion between carbohydrates and fat, enough protein and essential amino-acids, inorganic salts, vitamins, roughage, and, last but by no means least, variety and palatability. These things appertain to the food; there is also the human factor to be reckoned with: "Healthy and complete nutrition is infinitely more comprehensive than mere feeding, mere filling of the stomach. It connotes a healthy body in all respects."

Of the value of the modern propaganda for the promotion of health there can be no doubt; and in that propaganda the delivery of the Hastings Popular Lectures must play an important part. The British Medical Association has been fortunate in persuading such distinguished and eloquent members of our profession as Sir Berkeley Moynihan and Sir George Newman to give the first two of the series. Probably, however, even more could be done by the general practitioners of the country, whose sympathy and co-operation Sir George Newman is ever ready to enlist. From the point of view of hygiene the population may be divided roughly into two parts: those who, believing themselves healthy, do not bother their heads with any propaganda; and those who, having in their consciousness some small symptom of disability, are prone to let their imagination run riot on

any suggestions that seem applicable to their condition. Short of some system of compulsory and periodic medical examination for the whole community—a pitch of State control to which we have not yet risen—the general practitioner of medicine is really the only person who can guide the individual of either class in the preservation or restoration of health. His are the opportunities for impressing on the carelessly healthy the need for caution; and he alone is in a position to counteract the neurasthenia-producing effects of injudicious propaganda in those who are needlessly alarmed. With the help of the general practitioner it may be possible also to obtain an answer to some at least of the pertinent questions asked by this year's Hastings Lecturer in his discussion of the six pillars of healthy human nurture.

### GALL-BLADDER DISEASE.

It has been said that disease of the gall-bladder now bids fair to succeed appendicitis as the most popular subject in the literature of abdominal medicine and surgery. This view certainly gains support from the recent address by Professor D. P. D. Wilkie to the Ayrshire Division of the British Medical Association, which is published in our present issue at page 481, for the first of his general conclusions is that gall-bladder infection is probably the commonest of all abdominal maladies, particularly among persons of sedentary habits. It is interesting to note also that in his experience the results of gall-bladder infection are particularly serious in well-to-do patients, who are prone to spend years in trying "cures" which hospital patients are—as he remarks, fortunately for themselves—unable to afford. Thus in his large series of 452 operations performed on the biliary tract the average age and operative mortality among the 184 private patients were 54 years and 6 per cent., as compared with 46.5 years and 1.4 per cent. among 213 hospital patients. Here, then, as elsewhere, affluence is not always an unmixed blessing.

Like Sir Berkeley Moynihan, whose recent Mitchell Banks Memorial Lecture was published in the *British Medical Journal* of January 7th, 1928, Professor Wilkie brings forward new evidence that infection of the gall-bladder does not take place from the bile, and that treatment by antiseptics to disinfect the bile, and by washing out the gall-bladder contents, as by Lyon's method, is largely founded on erroneous premisses. But whereas the President of the Royal College of Surgeons of England laid stress on the lymphatics as the route by which infection reaches the gall-bladder, Professor Wilkie's contention, based on the work of Dr. A. L. Wilkie, is that there is an intramural infection of the gall-bladder derived from the blood stream, and that the lymphatics then pick up the infecting organism. Further, the responsible bacterium is, as Rosenow insisted some years ago, usually a streptococcus, and not, as has commonly been stated, *Bacillus coli* or the *B. typhosus*. The presence of the former is probably a secondary infection. The growth of the streptococcus is inhibited by the bile, and hence the failure to confirm Rosenow's results may be explained, for not only may the bile be sterile, but cultures of portions of the gall-bladder wall may remain negative from the action of bile adherent to the mucosa. Professor Wilkie, with due caution, indicates his suspicions about the aseptic production of a single pure cholesterol calculus, as described by Asehoff and Bacmeister, and, without

discussing the relation in point of time, states that in isolated examples of this condition a streptococcus has been found in the wall of the gall-bladder and in the centre of the calculus.

The diagnosis between gall-bladder disease and duodenal ulcer, especially in women, may clinically be so difficult that the term "cholecysto-duodenal syndrome" is appropriate. It is here that radiography gives most useful aid in coming to a right decision. Sercen examination during an acute attack may show immobility of the right half of the diaphragm, and Professor Wilkie's experience in more than 200 cases examined by Evarts Graham and Cole's method of cholecystography has convinced him that this is by far the most efficient means of diagnosis, since it gives the correct answer in over 90 per cent. of the cases. In the early stages, however, of chronic cholecystitis the functions of the gall-bladder may be so well carried out that cholecystography does not show any abnormality. We publish also in this issue a paper by Dr. J. F. Brailsford on the x-ray diagnosis of pathological conditions of the gall-bladder. Dr. Brailsford, who writes from an experience of nearly 500 cases, agrees with Professor Wilkie in advising a combination of cholecystography with a barium meal, and prefers the intravenous to the oral administration of tetraiodophenolphthalein, as more accurate in diagnosis, and safer, for he has had no more than five severe reactions. The superiority of cholecystography over an ordinary radiogram is shown by his estimate that only about 30 per cent. of gall-stones contain sufficient calcium to cast a shadow by the older method.

While admitting that *B. coli* infections of the gall-bladder may be favourably influenced by very large doses of hexamine, Professor Wilkie makes the point that in the majority of cases there is an intramural streptococcal infection for which no drug is effective, though a streptococcal vaccine would appear to be the most rational form of medical treatment. Well-established infection of the gall-bladder is, however, highly resistant to any but surgical measures, and he therefore advocates cholecystectomy, which, in his experience and that of many others, is not followed by any untoward results. He regards this operation as much more satisfactory than drainage on account of the liability to recurrences, after temporary benefit, experienced by patients who have undergone cholecystotomy. Here he is in evident agreement with Sir Berkeley Moynihan, who said in the Mitchell Banks Lecture: "I have no doubt that, until we are able clearly to understand and to control the earlier symptoms of cholecystitis and its foregoing conditions, removal of the gall-bladder should be performed more frequently than is now the custom."

For the time being, then, cholecystectomy appears to hold the field in the treatment of established biliary infection. In the United States it has become almost the routine procedure. Stanley Mentzer, in a recent survey of gall-bladder surgery based on a study of 14,000 specimens,<sup>1</sup> says that, whereas cholecystostomy formerly comprised more than half the operations upon the gall-bladder, to-day it comprises less than 5 per cent. in most of the clinics in America, cholecystectomy accounting for about 90 per cent. He regards the surgical treatment of biliary disease as fairly well stabilized at present. In his view, it should be based rather on the clinical symptoms than on the local pathological changes, and cholecystectomy is the operation of choice.

## HARVEY TERCENTENARY, 1628-1928.

THE tercentenary of the publication of William Harvey's epoch-making *De Motu Cordis* will be celebrated here from Monday, May 14th, to Friday, May 18th. The arrangements are in the hands of the Royal College of Physicians of London, and a programme giving an outline of the several functions and entertainments has now been issued in advance for the convenience of official delegates and others. The proceedings will open on the morning of May 14th with a reception of delegates by the King at Buckingham Palace. At 3 p.m. there will be a reception by the President of the Royal College of Physicians at the College (academic dress), when addresses will be presented by delegates, Honorary Fellows will be admitted, and eulogies of Harvey will be delivered. In the evening the Grocers Company will give a dinner to delegates and guests at their Hall in the City. On the mornings of May 15th and 16th demonstrations by the Royal College of Physicians will be given at University College, London, as follows: (1) a reproduction of Harvey's original experiments displayed cinematographically; (2) illustrations of some recent additions to our knowledge of the circulation. The principal functions on May 15th will be a luncheon party at St. Bartholomew's Hospital (of which Harvey was physician), given by the governors of the hospital; tea at the College of Physicians, with an exhibition of books, manuscripts, pictures, silver, and other objects of interest; and a conversazione in the Hall of the Merchant Taylors Company, at which H.R.H. the Prince of Wales has consented to be present. On the evening of May 16th there will be a dinner to delegates and guests given by the President and Fellows of the College of Physicians in the Guildhall of the City of London. May 17th and 18th will be devoted respectively to visits to Oxford, by invitation of the Warden and Fellows of Merton College, of which Harvey was Warden; and to Cambridge, by invitation of the Master and Fellows of Gonville and Caius College, whence Harvey graduated. Other entertainments for ladies accompanying delegates and guests are being arranged. Throughout the week preceding the celebration, including Sunday, May 13th, the secretary's office at the Royal College of Physicians, Pall Mall East, S.W.1, will be open daily from 2 to 5 p.m. for the issue of programmes, tickets, and other information. A full and detailed programme will be published in May, and may be obtained then on application to the College. The tercentenary is being celebrated this week in America by the College of Physicians of Philadelphia. Included in the programme are two commemorative addresses on Thursday, March 22nd—the Mary Scott Newbold Lecture by Sir Humphry Rolleston, Bt., on "Harvey's predecessors and contemporaries," and the Nathan Lewis Hatfield Lecture by Professor J. J. R. Macleod of the University of Toronto on "Harvey's experiments on the circulation."

## HISTORICAL EXHIBITION AT CARDIFF.

WE publish elsewhere in this issue a letter relating to the proposed historical exhibition at the Cardiff meeting of the British Medical Association in July next, which it is intended to make specially illustrative of Welsh folk-medicine. It is a matter for satisfaction that the History of Medicine Section of the Association is being continued this year under the presidency of Mr. W. G. Spencer; this section was formed for the first time last year in Edinburgh, and was very well attended. Edinburgh, we may recall, was the first University in this country to establish a lectureship on the history of medicine, and last year's president of the section was Dr. John D. Comrie, the lecturer on that subject. The museum organized at Edinburgh attracted an attendance of several thousand persons, and included an exhibit by the Wellcome Historical

Medical Museum of illustrations from ancient surgical manuscripts, a series of engravings of famous physicians lent by the Royal College of Physicians of London, many portraits of local lecturers and professors, as well as a collection of Lister relics organized in Edinburgh. The Cardiff exhibition in July will deal especially with Welsh folk-medicine, which should prove of great interest. Tradition says that Welsh medicine was practised by the ancient Cymry before they became possessed of cities and sovereignties in the time of Prydain ab Aedd Mawr. During his reign the learned men were divided into the three orders of Druids, Bards, and Ovates, of whom the Druids practised medicine and magic. In those early times wells, exercise, herbs, and magical incantations were the principal means of healing. At a later date Taliesin speaks of the liver, kidney, and the heart as being three intractable organs, and mentions disease of the knee-joints; disease of a rib, and phthisis as tedious complaints. Howel Dha, who lived about the time of King Alfred, drew up a code of laws, in which several references are made to the medical practitioners of the period, and in which the fees are fixed for such procedures as applying a tent, administering herbs to a swelling, and letting blood. Rhiwallon, one of the earliest authentic physicians of Wales, who lived in the thirteenth century, made a collection of medical recipes applicable to various diseases, and a manuscript of these has come down to us. Members of his family appear to have practised medicine in Wales down to the middle of the eighteenth century, and several of their medical manuscripts have been preserved, so that Welsh medicine has a character of its own. A manuscript of the fifteenth century mentions some eight hundred medicinal substances, including plants, flowers, and roots, of which many are still in use, although it includes also much animal pharmacy. This manuscript gives a list of the essentials for a physician, which are a lancet for bleeding and a larger knife; a steel or silver spatula; a bladder with pipe attached for injections; a collection of plasters, ointments, and pills; and a sheltered garden of trees and herbs where medicines may be grown. Much lore of a medical nature centres round the wild goat, and from the ancient beliefs about its remedial virtues has probably originated the practice, common in various parts of England till recent times, of keeping a goat among other farm stock because its presence was supposed to be healthy for cattle and to keep away disease. Mistletoe and selago were remedies which came down from Druidic times, much used in ancient Welsh medicine, and treated with great veneration. It is hoped that the influence of these and many other native Welsh remedies on medicine may be traced at the forthcoming museum, where doubtless many of the interesting Welsh manuscripts preserved in the National Library of Wales will also be exhibited.

## HOURS OF WORK IN FACTORIES.

THE most recent publication<sup>1</sup> of the Industrial Research Board is concerned with two separate problems in connexion with the hours of work in factories as they affect women. The first considers the advisability of breaking up the five-hour spell, where such is in vogue, by instituting a compulsory rest pause, and the second has reference to the effects on output, lost time, and labour turnover of the eight-hour double-shift system. Under the present factory law work may not be carried on for more than five hours without a meal interval, and, with the reduced hours now commonly worked, many firms have found it convenient to run the full time in the morning period. It is significant

<sup>1</sup> *Two Studies on Hours of Work: (I) Five-hour Spells for Women with Reference to Rest Pauses.* By H. M. Vernon, M.D., and M. D. Vernon, M.A., assisted by I. Lorrain-Smith, M.A. (II) *The Two-shift System in Certain Factories.* By May Smith, M.A., and M. D. Vernon, M.A. Medical Research Council. Industrial Fatigue Research Board Report No. 47. London: H.M. Stationery Office. 1928. 1s. 3d. net.

that the Factory Bills drafted by the present Government and its predecessor both proposed a limitation of four and a half hours for any spell, but with the proviso that if a stoppage of not less than fifteen minutes were introduced the period could be lengthened, under one bill, by the extension of the time of the stoppage by an equivalent period, and, under the other, to five hours. The need for authoritative information on the subject is therefore evident. The first investigation was made by Dr. H. M. Vernon and Miss M. D. Vernon, and covered a considerable number of factories and variety of trade processes. The advantages of a break during a five-hour spell are discussed from various aspects. Physiologically, nutrition is considered the most important factor, and evidence is produced to show that a five-hour morning spell means five and a half to six hours, or even more, without food; while, apart from allowing for the relief of hunger, it is held that the rest pause affords relief from physical fatigue. It is assumed that the psychological advantages may be even greater than the physiological advantages in the case of monotonous repetition work, and in support of this it is mentioned that three large establishments showed respectively an average of 25 per cent. "labour turnover" per annum where there was a fifteen minutes' break, 42 per cent. where there was a three minutes' break, and 94 per cent. where there was no break. Output is shown to be increased where the operations are wholly or mainly manual, but owing to the variability of sickness-producing factors it is admitted that the effect on health cannot be satisfactorily demonstrated. That there are valid objections to the break in certain processes is acknowledged, but it is thought difficulties could be overcome. It is finally suggested that ten minutes for a break would be preferable to fifteen minutes. The employment of women, and of young persons over 16 years, in two eight-hour shifts between 6 a.m. and 10 p.m. (6 a.m. to 2 p.m. on Saturdays) is permitted by the Employment of Women, etc., Act (1920), provided a joint application be made by employer and employed. Special conditions, chiefly relating to welfare, are attached to the permit by the Factory Office. The system originated during the war, when it was found to be preferable from the point of view of health to the working of overtime by women and young persons, and a departmental committee recommended its continuance. There is not much demand for these permits, and very few of those granted apply to a whole factory. Most are required for departments which cannot keep pace with others in production and as a substitute for overtime during periods of pressure, but a number are in force permanently at certain manufactories of hosiery and artificial silk. This part of the report was compiled by Miss May Smith and Miss M. D. Vernon; the investigations appear to have been carefully carried out, and the result shows that the system *per se* has very little adverse influence, if any, on workers or trade processes. Objections to it are mainly of a social nature.

#### GLAND GRAFTING.

THE subject of gland grafting has excited a considerable amount of interest within the last few years—not only in its application to man, but also to animals—and the claims made by Dr. Serge Voronoff have had a wide, and often uncritical, publicity in the popular and agricultural press. In the case of human beings critical experimentation is difficult, if not impossible, and variables which may enter into this investigation (other than those incident upon the actual operative intervention) cannot be measured or assessed—as, for example, the psychological effects on the subject. In animals, however, careful and exact scientific control is more easily possible, and the visit of a delegation of British scientists to Algiers to investigate Dr. Voronoff's

work on testis grafting on bulls and rams is of considerable interest; a report of this visit appears at page 505. In animals two sets of results are said to follow this operation. Old animals are rejuvenated and their reproductive powers restored; sexually immature animals have their growth and general vigour stimulated. Moreover, it is claimed that these characters are, in part at least, transmitted to the offspring. This last statement involves the acceptance of the hypothesis of inheritance of acquired characteristics; generations of scientists have as yet found no definite evidence in support of this hypothesis. From the medical point of view the rejuvenation of the senile male is of more importance than the acceleration of the growth and general vigour of the sexually immature. The delegation examined the available evidence, with every assistance from Dr. Voronoff himself, and, while it considered that the claim was possibly justifiable, it found that the evidence was not based on critical experimentation. It is very doubtful if either of the sets of experiments would be of any economic value to British stock breeders, but it is recommended that controlled experiments should be undertaken in this country in consequence of the scientific interest and the wide publicity which has been given to the subject. In view, therefore, of the unsatisfactory state of the evidence in animals, it would probably be unwise to conclude that grafting of testicular material in man—the delegation has not investigated the grafting of thyroid gland—is definitely advantageous; rather should it still be regarded as *sub judice*.

#### CONFERENCE ON RHEUMATIC DISEASES.

THE conference on rheumatic diseases, to be held at Bath on May 10th and 11th, of which we have already published preliminary announcements, bids fair to be an occasion of much importance, both by reason of the thoroughness of its programme and the authority of those taking part in the discussions. It will have something of an international character also, for among the expected speakers are medical men from France, Belgium, Holland, Sweden, and the United States. Sir George Newnan, Chief Medical Officer to the Ministry of Health, is to preside over the conference, and the vice-presidents include the Presidents of the Royal Colleges of Physicians of London, of Edinburgh, and of Ireland, and the Presidents of the British Medical Association and the Royal Society of Medicine. The conference is to meet in three sessions, to be held consecutively, the first dealing with social aspects, the second with causation, and the third with treatment. These sessions will be presided over respectively by Lord Dawson of Penn, Sir Humphry Rolleston, and Sir Farquhar Buzzard. The announced speakers are already so numerous—at one of the sessions a dozen—as apparently to leave little room for the open discussion with which, it is hoped, each session will conclude, but many voices can be heard in a three-hour sitting. Among the speakers dealing with social aspects are Dr. H. B. Braeklenbury, on the organization of medical treatment of industrial rheumatism, Dr. Alison Glover, on the general incidence of rheumatic diseases, and Dr. Reginald Miller, on the influence of environment upon infection. Two lay contributions will be made in this session—one by Sir Walter Kinneir, on the cost to the country of industrial rheumatism, and the other by Mr. W. A. Appleton, speaking from the standpoint of the approved societies. The speakers who will deal with causation include Dr. W. Langdon-Brown, on the endocrine factor, Dr. Carey Coombs, on rheumatic infection in children, Dr. Dingwall Fordyce, on predisposing factors, Dr. Geoffrey Hadfield, on the pathology of tissue reaction, Dr. C. W. Vining, on the pre-rheumatic child, and Professor Stockman; several visitors from abroad will also contribute to this

part of the subject, including Dr. Homer Swift, and Dr. Weif of Paris. The physical treatment of rheumatic diseases is to be dealt with by Dr. Gunzburg of Antwerp and Dr. Campbell McClure, surgical treatment in degenerative arthritis by Mr. Max Page, and acute rheumatic infection in childhood by Dr. F. J. Poynton. Sir William Willcox will speak on the treatment of underlying infection, and Dr. A. P. Thomson and Dr. R. L. J. Llewellyn will also take part. It is expected that many of those attending the conference will be delegates from local authorities, and with that in view the Ministry of Health, the Scottish Board of Health, and the corresponding departments in Northern Ireland and the Irish Free State have intimated that they will consider favourably applications for payment of expenses from local authorities who desire to be represented by their medical officers. The railway companies are issuing return tickets at a cost of a single fare and a third. No more appropriate centre could have been chosen than Bath, and the authorities of the spa, with their traditional hospitality, always very evident in the case of medical visitors, are giving a civic welcome at the opening of the conference and an evening reception. It need scarcely be said that the bathing establishment will be open for inspection, with demonstrations of the treatments. The honorary organizing secretary is Mr. John Hatton, director of the baths, and the honorary medical secretary is Dr. Vincent Coates, at 10, The Circus. Everything points to a notable assembly, one which should mark the pre-eminence of British medicine in grappling with this group of diseases, and we may look for contributions to the literature of lasting value.

#### SUPERANNUATION OF LOCAL GOVERNMENT EMPLOYEES.

THE Departmental Committee appointed in 1925 "to inquire and report whether any amendments are required in the Local Government and other Officers' Superannuation Act, 1922," has reported in favour of the compulsory establishment of schemes of superannuation by all local authorities, whether separately or in combination, on the lines laid down in the permissive Act of 1922.<sup>1</sup> It is recommended that participation in the schemes should be compulsory for all officers and non-manual employees, and optional for servants and manual employees at a lower rate of contribution than officers, the option in the latter case to be exercised through a ballot of the established servants of each authority. The committee recommends that the Poor Law Officers' Superannuation Act, 1896, should be repealed, and Poor Law authorities in general brought under the Act of 1922, as amended by the proposed legislation, existing Poor Law employees being allowed benefit of special rates of contribution related to the length of their Poor Law service. It is not, however, thought practicable to bring asylum officers within the terms of the Act of 1922, and in their case it is suggested that the Asylum Officers' Superannuation Act of 1909 should be so amended as to bring it into line with the Act of 1922 without abrogating the special benefits it confers on a special class of public servant. The committee rejects the proposal put forward by several witnesses, and pressed in particular by the British Medical Association in the interests of medical officers, that provision should be made for the addition of a period not exceeding ten years to the actual time served for the purpose of computing the amount of pension due to professional officers, who are placed at a relative disadvantage under the Act by their necessarily late entry into the local government service. Such a concession is permissible under several of the local Acts now in operation. The committee contends that compensation for the disadvantages of late entry should be rather by way of immediate higher remuneration than through conces-

sions in regard to superannuation, but realizes that the proposal for conceding additional years in the calculation of the minimum period of service entitling to pension is on a different footing. This is fortunate, since it will be sufficiently clear that the medical officer who enters the public health service with a D.P.H. and the three years' experience in medical practice considered desirable by the British Medical Association will not find it easy to complete the full period of forty years' service before the retiring age of 65. A modification in this age is suggested for nurses and health visitors, for whom compulsory retirement at 60 and optional retirement between 55 and 60 after a period of thirty years' service is recommended. Optional retirement between 60 and 65 after a similar period is proposed in the case of male nurses. The committee recommends that in the event of early legislation making the establishment of schemes obligatory, it should be open to any local authority by resolution to defer the day appointed for the coming into force of the Act for a period of five years. There is clearly no likelihood of securing the necessary legislation during the present session, and it is to be hoped that the period of grace accorded to local authorities will be modified in proportion to the delay in bringing in the measure.

#### A CENTENARY IN MEDICAL JOURNALISM.

THE completion of a century's continuous publication week by week is still an achievement rare enough in journalism to call for comment, and it is with pardonable pride that the editorial staff of the *New England Journal of Medicine*, formerly known as the *Boston Medical and Surgical Journal*, celebrates, in the issue of February 23rd, the attainment of its one hundredth anniversary. Actually this well-known American periodical can claim an older ancestry, for of the two publications which were merged into the *Boston Medical and Surgical Journal* when it first appeared in 1828, one—the *New England Journal of Medicine and Surgery and the Collateral Branches of Science*—was founded in 1812. Its title alone suggests an age when time and space—in the journalist sense—were things of less consequence than to-day. The other parent was the *Boston Medical Intelligencer*, which came into being in 1823, the year in which our British contemporary the *Lancet* was founded. Since those far-off days the *New England Journal of Medicine* has passed through the hands of many editors and proprietors, and it is now owned and published by the Massachusetts Medical Society, with Dr. Walter P. Bowers as managing editor. In the centenary number there are numerous articles dealing with the history of the journal and of medical science in America. Several reproductions of pages of the very early numbers serve to illustrate the advances which have been made in a hundred years in typographical method. There is a certain rich floweriness of expression in some of the articles reprinted which is seldom found anywhere to-day. We have read with particular interest the article on the history of medical journalism by Dr. Morris Fishbein, editor of the *Journal of the American Medical Association*, who recalls how his distinguished predecessor, Dr. G. H. Simmons, established a corps of manuscript editors, and laid down a typographical style for the publications of the American Medical Association, and in many other ways proved a stimulus to medical periodical literature in the United States. Dr. Fishbein ends with some maxims for the guidance of medical editors and their contributors. He exhorts the latter to be brief and interesting, and to publish only when they have something new to say or something old to say in a new way; to be as careful in literary publication as in surgical operation; to eliminate unnecessary charts, tables, and illustrations; to provide an adequate summary and conclusions; and to quote only from literature that they themselves have consulted.

## COLLECTIVE RESEARCH IN THE WEST COUNTRY.

## CONDITIONS PREDISPOSING TO RHEUMATIC INFECTION OF THE HEART.

In a recent review of some of the collective research carried out by the British Medical Association during the last sixty-five years we pointed out that there were other forms of collective investigation besides those described.<sup>1</sup> We are now able, through the courtesy of those responsible for its inception, to give some account of an inquiry into rheumatic infection of the heart, which is being carried out in the West Country under the most favourable auspices.

*Scope of the Inquiry.*

The scheme was outlined on page 701 of the *British Medical Journal* for October 15th last, and has now been working for four months with the enthusiastic co-operation of all concerned. The district covered, which includes the counties of Gloucestershire, Somerset, and Wiltshire, has for some time been regarded as a rheumatic area, and a good deal of work on rheumatism had been done in Bristol, Bath, and elsewhere before the inception of the present scheme. For several years also the area has been happy in the existence of a large measure of the co-operation between public and voluntary medical services essential to the development of any such scheme. Hospital physicians and school medical officers have been in cordial co-operation for several years in both Bristol and Bath, where physicians have been working with school medical officers in the selection of children with cardiac diseases for special treatment; in Gloucestershire the well-known plan of Dr. Middleton Martin has been in operation, while both in Somerset and Wiltshire orthopaedic and other organizations furnished a useful precedent. The area is, moreover, peculiarly suitable for the investigation because it offers a wide range of conditions, economic as well as geographical. It includes sea-board, fenland, high moor, chalk downs, limestone ranges, and coal measures, with large industrial cities and rural communities of every size.

The actual scheme had been under consideration for several years when, after some unsuccessful attempts at enlisting the support of powerful organizations, an appeal was made in 1926 to the Cardiac Subcommittee of the Science Committee of the British Medical Association, which approved the project and recommended it to the Medical Research Council, by whom the clerical expenses of the work are now covered. The plan also interested Sir George Newman, who, as Chief Medical Officer to the Board of Education, was glad of the support offered in dealing with the cardio-rheumatic children attending the elementary schools. The county and borough medical officers for the area having been consulted, on his advice the support of the local authorities was secured and the work definitely set on foot on October 1st last.

*Basis for Notification and Registration.*

At the outset those responsible for the inauguration of the scheme had to decide upon the basis for notification and registration for the purposes of the investigation. In the various inquiries already made into the geographical and seasonal incidence of rheumatic fever, valuable results have been furnished so far as the seasonal incidence is concerned. Inquiry into the geographical distribution, however, has shown the difficulty of securing general agreement, over an area wide enough to be useful, upon a definition of the disease that is to be studied. The position is illustrated by the parallel case of pneumonia, in which notification has proved useless as a basis for scientific observation of a group of diseases simply because what one man includes under the term "pneumonia" another would exclude. And yet it is impossible to make headway with the prevention of infectious disease without knowledge of the conditions under which it comes into being. Nor can this be secured without the general co-operation of medical practitioners over a large area. After considerable discussion of the problem it was decided that if really valid data were to be secured under the present scheme it

must be through voluntary as opposed to compulsory registration. On this basis all the practitioners in the area covered were asked to co-operate in the registration of cases falling within the following definitions:

- (1) Heart disease arising in connexion with rheumatism, chorea, or scarlet fever in children between the ages of 5 and 14 inclusive.
- (2) Heart disease which, though not arising in connexion with rheumatism or chorea, is nevertheless rheumatic in type—that is, ventricular enlargement with mitral incompetence, with or without aortic incompetence, or acute pericarditis arising in children between the ages of 5 and 14 inclusive.

Various bodies of medical men were consulted as to the development of the scheme, and on the advice of the Medical Advisory Committee to one of the county councils it was decided not to offer practitioners any fee or honorarium for their reports. The local Branches and Divisions of the British Medical Association approved the proposals, as did a meeting of the South-Western Division of the Society of Medical Officers of Health. Through the medium of the medical officers of health of the counties and boroughs arrangements were made whereby the registration of cases by private practitioners would be supplemented by selection of cases from among the children attending the public elementary schools.

In order to standardize as far as possible the type of case accepted it was fortunately possible to offer to the school medical service the assistance of hospital physicians with special experience of the disease, to decide whether to accept or reject doubtful cases. The various local authorities agreed to recommend the necessary expenditure on condition that the physicians concerned also offered their opinions as to the treatment of the children examined. This it has been possible to arrange for a survey by physicians of experience of elementary school children under suspicion of heart disease. The local authority is advised by these physicians whether a child is or is not fit for school, whether games or drill should be allowed, whether institutional treatment is desirable, and so on. As a general principle it is understood that the closest possible touch is maintained with private practitioners in charge of such children, and they are offered the consultative services of the physicians at their respective clinics in cases of suitable social status. Arrangements are being made for groups of children to be assembled not only at the physicians' own hospitals, but also at suitable centres in outlying districts. In Gloucestershire Dr. J. R. Collins and Dr. D. E. Finlay are undertaking this work, in Somerset Dr. C. E. K. Herapath, and in Wiltshire Dr. Vincent Coates. Similar work is being carried on in the city areas concerned, by Dr. Vincent Coates in Bath, by Dr. D. E. Finlay in Gloucester, by Dr. R. C. Monnington in Salisbury, and by Dr. Carey F. Coombs (who was a member of the Association's Cardiac Subcommittee referred to above) in Bristol.

At first the intention was to limit the inquiry to cases in which the infection of the heart might be presumed to have arisen on or after October 1st, 1927. Experience of the work has, however, shown that it will be more profitable to collect all available cases of rheumatic heart disease arising between the prescribed ages, and make inquiry into the home conditions whenever this is possible in order to be sure where the disease began. This must in some instances be impossible, but many of the children have lived in one house only, and in many the beginning of ill-health can be dated with accuracy, so that in one way or the other a majority of those registered should be available for environmental inquiries. The next step after registration of the case, whether it comes from the private practitioner or through the school medical service, is to make these inquiries. Till now the medical man in charge of the case has been asked to do this; but experience suggests that this is a good deal to ask of a man who has already taken the trouble to fill up and post the form on which the case is reported. It is probable, therefore, that in future he will not be troubled with the questionnaire as to environmental conditions unless he expresses a wish to fill it up. The details asked for on this questionnaire are entrusted to the staffs of the county health departments and assembled at their several offices.

The co-ordinating point between every agency concerned is at the Bristol General Hospital, where the University

<sup>1</sup> *British Medical Journal Supplement*, December 31st, 1927, p. 246; January 7th, 1928, p. 2.

has been instrumental in forming a centre for cardiac research with the aid of grants from the R. L. St. J. Harmsworth Memorial Fund and the Colston Research Society and other bodies.

#### *An Encouraging Response.*

The scheme has now been in action for four months, and the response secured has been most encouraging. The practitioners of the area have sent in a good many reports, and it is not likely that many cases arising during the period of the inquiry have missed registration. The medical officers of health and the school medical officers, together with their auxiliary staffs, have taken the matter up with great keenness. Finally, the physicians concerned are much to be congratulated on the public spirit with which they have undertaken a task which brings them in little except hard work and a certain artistic satisfaction. It is believed that work undertaken voluntarily after this fashion will furnish more reliable results than any amount of records obtained under a compulsory system, and will, moreover, afford an excellent opportunity of testing the potentialities, alike for treatment and for prevention, of that co-operation between the three sections of the profession—general practitioner, administrative officer, and consultant—which seems to flourish best in an atmosphere of complete freedom.

### SOME PROBLEMS OF NEPHRITIS.

GOULSTONIAN LECTURES BY DR. T. IZOD BENNETT.

THE Goulstonian Lectures for 1928, on "Some problems of nephritis," were delivered at the Royal College of Physicians of London by Dr. T. IZOD BENNETT on March 13th, 15th, and 20th.

#### *The Problem of Uraemia.*

Dr. Izod Bennett mentioned first the great variety of symptoms included by different writers under the heading of uraemia. He distinguished between cases in which the two ureters became simultaneously blocked, with resulting gradually deepening coma, and the train of symptoms which marked the termination of cases of nephritis with gastro-intestinal manifestations, muscular twitchings, convulsions, and hyperpnoea. Dr. Bennett described in detail a case of the latter type which resulted from bilateral cystic disease of the kidneys. This patient first came under his care in 1923, and was the willing subject of many observations until she died after the acute onset of uraemia in 1927. This case was an example of uraemia without nephritis, and was therefore of especial interest. The patient's main symptoms until the final phase were progressive weakness, anorexia, and a foul, sour taste in her mouth, possibly due to the increased ammonia and urea content of her saliva. She never exhibited hypertension or oedema, and had no nervous symptoms until the last five days of her life, when coma and convulsions supervened. Discussing the causation of uraemia as exhibited by this case, Dr. Bennett first reviewed the theory of nitrogen retention which had attracted so many observers since the days of Bright, and summarized the chief evidence against such retention being the cause of uraemia—namely, the fact that the administration of urea and kindred substances to animals did not produce uraemia; the occurrence of conditions such as cystic disease of the kidney or prostatic obstruction, often persisting for many years with marked nitrogen retention, but no evidence of uraemia; and the occasional discovery of cases of uraemia without nitrogen retention. Passing to the question of non-nitrogenous substances the lecturer drew attention to the retention of phosphates and even of sodium chloride in uraemic patients, which had occurred in the case of his own patient. Despite this and other evidence he did not think that at present any direct relation had been established between the accumulation of any of these chemical substances and the nervous phenomena of uraemia.

Dr. Bennett next quoted work which indicated that acidosis, in the sense of a lowering of the alkali reserve of the blood, could be demonstrated in all cases of uraemia, and especially in those with marked nervous and respira-

tory symptoms. In his own patient this decrease in the alkali reserve of the blood was a marked feature in the final phases, although the administration of large doses of sodium bicarbonate caused temporary increase without, however, complete disappearance of the muscular twitchings, and without preventing the onset of coma and convulsions. This suggested that acidosis was not by itself a cause of uraemia, and in considering other aspects of blood chemistry the question of the blood calcium content became of importance, although there were many difficulties, particularly with regard to the actual physical state of calcium in the blood. The increase in the phosphate content of the blood in uraemia was found to be associated with a diminution in the amount of calcium, and the low figure of 6 mg. per 100 c.cm. had been obtained during the final stages of the illness in the case described.

Dr. Bennett then went on to deal with other clinical states in which the blood calcium was diminished and in which the symptoms of tetany appeared; he cited non-malignant pyloric stenosis, parathyroid deficiency, chronic diarrhoeal states, rickets, and poisoning by overdoses of alkalis. In this group of cases alkalosis first developed, and the other conditions of tetany and diminished blood calcium were also present. It appeared also from therapeutic considerations that calcium shortage was the common factor in all cases of tetany, and it was suggested that there was a true relation between the twitchings and convulsions of uraemia which was associated with a low blood calcium and the nervous phenomena known as tetany. There appeared to be a disordered metabolism of calcium in both conditions, and it was interesting to observe that in some cases of non-malignant pyloric stenosis degenerative changes occurred in the renal tubules, showing that chemical changes in the blood might themselves exert a destructive effect upon the kidney substance. Turning next to certain experimental work Dr. Bennett described the effects of forced rapid ingestion of large quantities of water in animals, which resulted in twitchings and convulsions leading to coma and death. In such cases water was absorbed too rapidly to be dealt with by the kidneys, and the final symptoms were very similar to those of the late stages of renal disease. Other experiments had shown that a syndrome indistinguishable from uraemia was produced in animals by the injection of sodium chloride solution in the presence of acidosis, without any renal lesion being present before or after. It was suggested that in these experiments the convulsions were due to a disturbance of calcium metabolism. In conclusion Dr. Bennett referred to the difficulties of exact work without repeated lumbar punctures, although analysis of the cerebro-spinal fluid in the case of his patient had given figures similar to those of the blood, but usually less marked in degree. He quoted Bright's observations on the importance of the chemical aspects of the subject, and expressed his own indebtedness to his laboratory colleagues.

#### *The Problem of Oedema.*

In his second lecture Dr. Bennett considered the problem of oedema; he admitted at the outset that the complexity of the subject made it impossible to form a judgement from personal observation alone, but careful study led to the conclusion that when oedema occurred in a case of nephritis it was evidence of the existence of an extrarenal factor which might explain the nephritis, but was never the consequence of nephritis. The balance of the evidence to-day was against oedema ever being the direct consequence of disease of the kidney, though it was possible that the cause of the oedema might also provoke disease of the kidney. Bright had called attention to the association of albuminuria, oedema, and disease of the kidney, but he had been more cautious than many of his followers in dogmatizing about the exact relation between these conditions.

Dr. Bennett then contrasted the two main varieties of nephritis under the names of hydropigenous and azotaemic types, and commented on the difficulty of explaining how disease of the kidney produced such divergent results. The type referred to in this country as "chronic parenchymatous nephritis" was supposed to be an example of a derangement of the capacity of the kidney to excrete sodium chloride; in support of this it was said that

administration of salt to patients with so-called renal oedema increased the oedema, while a salt-free diet often reduced it. It was certain, however, that the blood chlorides were not increased in renal oedema, and the diminished excretion was even more marked in cases of cardiac failure or pneumonia, where the renal function was not interfered with. It appeared more likely that there was in renal oedema a "prerenal deviation" of both water and chloride, that there was an extrarenal cause, and that the salt-retaining kidney must be dismissed as a myth. In the final stages of renal disease an increase in the chlorides often became apparent, and marked examples of such retention were also found in mechanical obstruction of the ureters, but oedema was usually absent in these cases, despite the high blood chloride.

An illustrative case was then demonstrated—a man, aged 22, who first came under observation for generalized oedema in August, 1926. The urine of this patient contained large quantities of albumin, but the figures on blood analysis showed a normal content of nitrogenous bodies and of the chlorides. A high protein diet and the administration of urica had resulted in a marked improvement, and the man was back at work with only slight oedema now, but his urine still contained large quantities of albumin. This case, Dr. Bennett said, was an example of the class of kidney disease now called "nephrosis"; it exhibited the characteristic features of a urine containing certain lipid substances which were doubly refractive, and also the excessive amount of cholesterol in the blood. This constant relation between oedema in renal disease and a high plasma cholesterol had been well established, but probably these were not related as cause and effect, some toxic disease acting on the reticulo-endothelial system being a possible underlying cause of both conditions. The kidneys in such cases of nephrosis contained very large quantities of cholesterol in the tubules, and, histologically, there were degenerative changes in the tubules, with little, if any, in the glomeruli. It was difficult to believe that such cases were examples of any primary disease of the kidney, although secondary changes in a kidney clogged with cholesterol esters might be expected, and did occur. The evidence was also against the hypercholesterolaemia being an effect of renal damage. Returning to the subject of oedema Dr. Bennett then dealt with the relation between the albuminuria and the oedema of kidney disorders. Epstein's view was that the loss of albumin from the blood plasma lowered the osmotic pressure in the blood, and water passed to the tissues. The high protein diets in such cases certainly often succeeded in reducing the oedema, but the theory did not explain the oedema occurring in other conditions, and there were cases of nephritis in pregnancy and acute cases of glomerulo-nephritis where the oedema was out of all proportion to the daily amount of albumin lost. Further, in the case demonstrated, loss of albumin continued although the oedema had largely disappeared. Albuminuria did not, therefore, explain the oedema of such cases.

Dr. Bennett then considered certain diuretics for the indirect light they might throw on the subject of oedema. He said that there was a school of thought which held that acidosis was an important feature of oedema; the treatment of such cases by alkaline diuretics had received much attention for many years. Very large doses might have to be given, but the results were often remarkable. In contrast with this line of treatment diuresis had also been achieved in desperate cases by the use of calcium chloride, although the acidity of the urine was actually increased. Thus both acids and alkalis could produce the same effects, and this paradoxical result might be explained by work which showed that any measure which tended to alter the titre of the renal blood acted as a stimulus to the renal cells. The work of the kidney in cases of oedema was possibly, therefore, directed to compensating an existing derangement of the normal blood chemistry, and though the strain of such compensation might damage the kidney the primary pathological process was an extrarenal one.

Dealing with experimental oedema, Dr. Bennett stressed the artificial nature of many such experiments and the dissimilarity between such oedema and that seen in pure lipid nephrosis. He thought that the work as a whole

tended to support rather than challenge the belief that "renal" oedema was of extrarenal origin. With regard to oedema in general there appeared to be no theory before the medical world to-day which explained all the known facts, but the theories which depended on the hypothesis that the oedema was a direct consequence of renal injury broke down almost from the outset. Elwyn had suggested that "renal" oedema was the result of an attempt to keep the blood volume constant, and this again would necessitate an extrarenal cause for the primary conditions. In all such cases it was necessary to search for some pathological change of a wide nature in tissues other than the kidney. Such a change was not the result of nephritis, although it was probable that the renal and the extrarenal damage had a common cause.

#### *The Problem of Hyperpiesia in Nephritis.*

In his third lecture Dr. Bennett pointed out that in the case of high blood pressure in its relation to nephritis there was an absence of essential data, and he emphasized that the patient discussed in his first lecture and the one shown in his second lecture had exhibited no hyperpiesia in the course of their renal disease. He classified the cases in which hyperpiesia was most marked into three groups, and dealt first with "chronic interstitial nephritis." Two cases described by Bright in his Goulstonian Lectures were first quoted to show that Bright had been puzzled by the frequent association of sclerotic kidneys and cardiac hypertrophy, and by the irregularity of albuminuria in such cases. Such subjects were examples of the classical arterio-capillary fibrosis described by Gull and Sutton, and it had been shown convincingly that in an enormous number of cases of contracted kidney there was evidence of high blood pressure for many years before any renal lesion became manifest. The etiology of this condition of "hyperpiesia" or "essential hypertension" was still obscure, but the present evidence and the anatomical changes in the kidney were against the theory that hypertension was primarily due to a disorder of kidney function. There appeared to be three stages in the development of the disease. There was at first a stage with the systolic blood pressure in the neighbourhood of 200 mm. of mercury and left-sided ventricular hypertrophy, but with no other signs or symptoms for many years. Next, the progressive disease of the arterioles in the renal tissues led to a "compensated renal failure," with polyuria and a urine of low specific gravity and a low concentration of urea, but without changes in the blood chemistry. In the final stage the retention of waste products of protein metabolism began to be in evidence until the patient died of uraemia, red sclerotic kidneys being found at the necropsy. In summing up this group of cases Dr. Bennett emphasized that the disease of the arteries had produced secondary changes in the kidneys because hyperpiesia invariably preceded all signs of renal disease, and because many patients died from other consequences of high blood pressure without having exhibited albuminuria or any other evidence of renal involvement.

The second group of cases comprised the renal complications of pregnancy. Dr. Bennett described eclampsia as merely a syndrome in a group of cases with certain manifestations due to renal disorder, and with severe generalized convulsions which made their appearance at some time close to the moment of parturition. It had been established that an elevation of blood pressure was almost invariably present in such cases. This rise in blood pressure was not usually excessive, and in the majority of cases it fell to normal after parturition, although occasionally the elevation might persist or increase. Another group of patients exhibited albuminuria and oedema without convulsions, and despite some difficulties associated with the method of classification of such cases it was possible to assert that in the majority elevation of the blood pressure was present. The important problem whether the hypertension or whether the result of the renal complications of pregnancy or whether it was present prior to any symptoms could not be settled owing to lack of information. Dr. Bennett thought that the term "toxæmia of pregnancy" was a good one, since it tended to keep to the front the general nature of the disorder in which the renal manifestations were part of the whole, and he mentioned work which suggested that an

arterio-spastic condition was the possible cause of the high blood pressure in these pregnancy cases.

In the third group of cases Dr. Bennett dealt with acute glomerulo-nephritis, in which elevation of blood pressure was present, though not in the focal type. The incidence of hyperpiesia in this condition was, however, not certain owing to a lamentable lack of evidence. It appeared that oedema was an accompaniment of all such cases in which it occurred, and in the majority the blood pressure returned to normal after the acute attack. While of a moderate degree in most cases of diffuse nephritis, the elevation of blood pressure was marked in some, and in these it was probable that the blood pressure was already high prior to the acute attack, and would usually persist. In cases with chronic diffuse nephritis, resulting from repeated acute attacks in many instances, a progressive elevation of blood pressure usually occurred, but it was seldom as marked as in cases of "essential hypertension," and occasionally it was completely absent. Dr. Bennett then went on to deal with the important question of whether a renal lesion could by itself produce an elevation of blood pressure. On physiological grounds the answer might be expected to be "Yes," but it had to be remembered that the kidney possessed considerable powers of reserve. The balance of evidence, however, based upon extensions of Rose Bradford's classical experiments, was that destruction of sufficient renal tissue was followed by a rise in blood pressure; even so, the mechanism by which such a rise was produced had not been established. None of the nitrogenous constituents of the urine had been shown to increase the blood pressure when present in excess in the blood. It was possible to have such an excess of cholesterol in the blood with a normal blood pressure, and the search for a pressor substance in the kidney itself had been unsuccessful. The evidence showed that hypertension due to renal disease was slight in degree, and when patients exhibited extreme degrees of high systolic blood pressure—200 mm. or higher—there was strong evidence for an extrarenal factor.

In conclusion, Dr. Izod Bennett pleaded for a wider outlook in the consideration of kidney disease. The renal function could be readily influenced by slight changes in the blood, and even by heat and cold directed to the surface of the body. He pointed out that at the time when Bright made his observations alcoholism was prevalent to an extreme degree in this country; this might explain to some extent the differences between the picture of nephritis drawn at that time and the form it exhibited to-day. He emphasized that the whole body and its metabolism should be studied in renal disease.

### ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the committee fifty-four cases were considered and £957 voted to forty-nine applicants. The following is a summary of some of the cases relieved.

Daughter, aged 44, of M.D. who died in 1908. Her father lost all his money, and the applicant, though delicate, trained as a nurse, which profession she followed until she had a serious breakdown through war work. She has tried several times to resume work, but is now suffering from tuberculosis. Only income £40. Lives chiefly with friends. Voted £26.

Widow, aged 65, of M.R.C.S. who died in 1903. Applicant and her daughter lived together until the daughter, aged 37, was removed to a mental hospital, and her income of £70 per annum has now to be used for her maintenance in the hospital. This leaves the applicant with only £26 per annum allowance from her sister-in-law, who also pays the rent. Voted £26.

L.R.C.P. and S. 1893, aged 73; wife aged 74. One son, who is married with one child, has started a small preparatory school. Applicant had to give up his practice two years ago on account of deafness, and has exhausted his savings. Only income the old age pension. Voted £40.

L.R.C.P. and S. aged 92, widower, as a result of losing all his money had to restart practice, though too old now to work, and last year made £173. He received gifts to the amount of £25. Voted £40 in quarterly instalments and a special grant of £15.

Daughter, aged 45, of L.R.C.P. who died in 1886. Both she and her sister have supported themselves by teaching in schools; the applicant is now bedridden owing to rheumatoid arthritis, and is entirely dependent on her sister. Voted £26.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, at 11, Chandos Street, Cavendish Square, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

## CONTROL OF CONCEPTION.

### INTERNATIONAL MEDICAL GROUP'S FIRST REPORT.

Those who attended the World Population Conference at Geneva in September last included representatives of medical science from a large number of countries in Europe and elsewhere, and among the offspring of the conference was the International Medical Group for the Investigation of Birth Control. This organization was the result of an informal meeting of medical representatives of different countries; it consists exclusively of medical practitioners, and aims at co-ordinating biochemical, physiological, and statistical research bearing upon contraception, and disseminating this knowledge so as to make it available to all countries.

The qualifications required of persons collaborating in the work, apart from adequate professional status in their respective countries, are defined as including "a detached and critical attitude to the methods now practised." They should be "people free equally from prejudices against birth control springing from religious or political beliefs and from prejudices in favour of it arising from excess of propagandist zeal." The headquarters of the committee are in England, and its efforts are to be restricted to collecting and circulating the communications received. The organization undertakes to act, not as a propagandist body, but essentially as a medical information committee, and in this capacity it will, no doubt, be welcomed by all who are interested in this debatable subject. That there is need for co-ordinated scientific study is demonstrated in the first result of its labours—a circular obtainable from the Hon. Mrs. Marjorie Farrer, secretary of the committee, 41b, Clanciarde Gardens, London, W.2.

This document contains the replies received from Dr. Alma Sundqvist (Stockholm), Dr. J. H. Leunbach (Copenhagen), and Dr. H. Riese (Frankfurt), representing Sweden, Denmark, and Germany respectively, to a questionnaire issued by the committee. Dr. C. P. Blacker (Dorking) deals with the position in Great Britain, and contributes an editorial note stating that it has been considered expedient to publish this, the first, report without waiting for a reply from the United States. It is intended to widen the circle of correspondents by degrees, and to publish the collected communications quarterly. Each communication is expected to include reports on (a) statistical investigations regarding the reliability, harmlessness, simplicity, or otherwise of different contraceptives; (b) research work of an immunological, biochemical, or physiological nature bearing upon the problems of contraception and sterility; and (c) information touching the general attitude of a country towards birth control, changes in this attitude, and in that of the medical profession.

The scope of the inquiry proposed is therefore comprehensive, but the first results are somewhat disappointing. No doubt as the movement gains headway and the various correspondents, as the result of experience, are able to devise a uniform method there will be a marked improvement, but in these first communications there is a divergence in style and treatment which makes comparison difficult. To some extent, of course, this is due to the inadequacy of the material available. The Swedish communication, for example, consists of rather less than two hundred words. Dr. Sundqvist cannot give any statistical information or any news of recent research. He states that the public attitude is enlightened and tolerant, that the law against giving public information about contraceptives is a dead letter, and that the members of the medical profession are, as a rule, rather indifferent. "Birth control," it would appear, is not a live subject in Sweden.

The writers of the Danish and German reports devote themselves largely to contraceptive methods. Dr. Lennbach states that more than three years ago he opened a contraception clinic in Copenhagen. His experience in dealing with about 2,000 cases has led him to conclude that cervical pessaries are suitable only for from 5 to 10 per cent. of all women, and he has therefore abandoned the "pro-race" and "Ramses" types of pessary in favour of the Dutch type. He states that in 800 cases fitted in the year ended October, 1927, he has so far had only three failures, but points out that as the period is short it is difficult to draw any certain conclusion from the figures.

The German report is less detailed, for the author, Dr. Riese, does not restrict the scope of his birth control clinic

to contraceptive methods. The technique which he recommends, after having tried and abandoned many methods on account of their unreliability and possible harmfulness, is the employment of a suppository in a gelatin base and the fitting of a pessary, generally a "Ramses." His practice, therefore, differs from that of Dr. Leunbach in two important points, for the Danish authority has come to the conclusion, after an examination of the effect of various spermaticides and suppositories on living spermatozoa, that all contraceptive suppositories are practically worthless, and he has also rejected the "Ramses" type pessary as generally unsuitable. Dr. Blacker's summary of the available British evidence on this point does not appear to clarify the position. He states that at the nine centres of the Society for the Provision of Birth Control Clinics, and at that of Dr. Norman Haire, the Dutch type of pessary is used, while at the Marie Stopes clinic the "pro-race" cervical type is employed with, it is claimed, a minimum of 1 per cent. of failures. Dr. Haire, however, is quoted as stating that the "pro-race" pessary failed in 88 per cent. of the cases he had seen.

Statistics regarding the relative efficiency of various types of pessary and of various spermaticides have not, Dr. Blacker points out, been yet impartially assembled and compared in Great Britain. The same may be said with even greater truth

of these offered in other countries. He adds that the Birth Control Investigation Committee, which is associated with the International Committee, is beginning to conduct researches which will yield more complete and detailed data than any that have yet appeared in England. The report for Great Britain seems to cover the ground more thoroughly than any of the others.

The publication of this first report of the International Committee should do something to stimulate a wider application of scientific study to this subject and the collection of trustworthy data on a broader basis. The lack of definition in statement is a weakness which can only be overcome as the material available is increased. In conclusion, it may be remarked that the members of the committee seem by implication to have restricted their studies to the use of contraceptive appliances and substances. Dr. H. Riese, their German correspondent, has, however, opened up a wider field which may be of even greater interest to the medical profession in Great Britain. In introducing his memorandum he states that, in his experience, contraception in extremely poor families, with many children and little sense of social responsibility, is generally performed by tube resection; and later, after describing the method of "birth control" attributed to him above, he suggests that temporary sterilization by injection of a contraceptive hormone would be preferable.

## Canada.

[FROM OUR SPECIAL CORRESPONDENT.]

### Professor A. B. Macallum.

THE retirement of Professor A. B. Macallum this year from the chair of biochemistry at McGill University marks the close of a brilliant teaching career extending over half a century. On the occasion of his last lecture to his students this month, with which he concluded his academic career, he received many marks of respect and esteem from the faculty and students. He had always devoted himself to physiology, but came to take more and more interest in the chemical aspect. He was the first to occupy the chair of biochemistry at the University of Toronto, holding this appointment from 1906 to 1917. He then served as chairman of the Advisory Council of Scientific and Industrial Research until his appointment in 1920 to the chair of biochemistry at McGill University. His many degrees and publications are evidence of his varied activities and achievements, and among them all he retained a love for the classics which contributed in no small degree to his influence in teaching. It was characteristic that in his final lecture (on vitamins) he should conclude by urging his students to acquire the habit of hard work and the spirit of inquiry, leading to them the passage from Tennyson's *Ulysses*:

"I am a part of all that I have met;  
Yet all experience is an arch wherethro'  
Gleams that untravelled world, whose margin fades  
For ever and for ever when I move."

He would have them

"Follow knowledge like a sinking star  
Beyond the utmost bound of human thought."

### Government Travelling Clinics in Alberta.

A great deal of work was done in 1927 by the travelling clinics organized by the Provincial Government of Alberta, and the country members are agitating to have the plan extended to cover the whole province instead of the northern part only. Whether or not this is the beginning of what may develop into a form of State medicine there is no doubt that the demand for such clinics has been created, and their activities will probably be widened. Each clinic includes three nurses, two doctors, and a dentist. One of the nurses travels ahead, examining the school children. Then the clinic comes in, but only on invitation from local committees interested in the schools of the district. The work undertaken is the removing of tonsils and adenoids, and the filling and extracting of teeth, and one of the doctors stays behind for a day for the after-treatment. The prices charged are 15 dollars for the removal of the tonsils and adenoids, 50 cents for

extraction of a tooth, and 1 dollar for an ordinary filling. The Minister of Health for the province sees no great difficulty in reconciling the work of the clinic with that of the local practitioners, as he showed that the clinic would probably only visit one place in a year. There is, however, still some dissatisfaction in the minds of local medical practitioners, both as to the actual working of the clinic and the possibilities implied in its growth.

### Chiropractors in Quebec.

There has been an attempt to introduce legislation by which chiropractors would be incorporated as a body possessing a definite status in the province of Quebec. The Provincial College of Physicians and Surgeons was fully advised of the matter, and steps were taken for concerted action on the part of the College and the medical schools of the province to place their views before the legislature. Accordingly, representatives of these medical bodies were sent to Quebec, and it was made clear to the Legislative Council that they were strongly opposed to any such incorporation being permitted. As a result of these representations the Council definitely refused the request of the chiropractors. In this respect the province of Quebec has taken a different stand from that taken by the province of Ontario, which has passed a bill by which all cults of this nature are placed on a footing defined and controlled by the Provincial Legislature.

## Union of South Africa.

[FROM OUR CORRESPONDENT IN CAPE TOWN.]

### Medical, Dental, and Pharmacy Bill.

DURING the last session of Parliament the Medical, Dental, and Pharmacy Bill passed its second reading and reached the committee stage. In committee seventy-five of its ninety-six clauses were disposed of when Parliament adjourned, and the Minister of Public Health agreed to the postponement of the bill only on the understanding that it should be proceeded with in the present session at the stage where it was interrupted in committee, instead of being introduced *de novo*. When recently consideration of the bill was resumed, Clause 76, promising to be somewhat contentious, was passed over for the time being, and the remaining clauses were adopted with little or no discussion. During the debate on the first day chief interest centred in a new clause introduced by the Minister to follow Clause 79, as follows:

"(1) No person registered under this Act shall himself make or attempt to make or to recover, or shall enter into any agreement or associate himself in any way with any other person for

the purpose of making or fixing, excessive or extortionate charges for any service rendered or to be rendered or for any article supplied by him by virtue of being so registered.

"(2) Unless the circumstances are such as to render it impossible so to do, every person registered under this Act shall, before rendering any service by virtue of being so registered, inform the person to whom the service is to be rendered, or the person in charge of such a person, of the fee which he intends to charge therefor: (a) when so requested by any person concerned; or (b) when such fee exceeds that usually charged for the service.

"(3) Any registered person who contravenes or fails to comply with any provision of this section shall be guilty of improper or disgraceful conduct within the meaning of Chapter IV of this Act, and it shall be the duty of the Council or the Board to take cognizance of and deal with such conduct under that chapter."

The clause was regarded by certain members with suspicion, but the general feeling seemed to be that it had been drawn up by the Minister to placate certain of the keenest opponents of the bill, who had endeavoured to establish a fixed scale of fees for medical practitioners. Replying to a somewhat long-drawn-out debate the Minister stated that far from the new clause being a slur on the medical profession it had proved acceptable to the Medical Association of South Africa, to which body it had been submitted. Legislation, he maintained, was necessary, not for the ordinary medical men, who stood very high in South Africa, but for the few exceptions. On a division the clause was adopted by 58 votes to 31.

Another new clause, introduced by Mr. J. D. Heyns, member for Middelburg, was to the effect that if a patient died during the administration by a medical practitioner of chloroform, or anything of a similar nature, an inquiry should be held by a magistrate. Although it was made clear that under the proposed clause there would have to be a *post-mortem* examination in every case of death under an anaesthetic, even though it was self-evident that no necessity for such existed, the mover of the amendment insisted that he wished to see an investigation made by a person not belonging to the medical profession in order to protect the public. The clause, after being redrafted by the Minister, was adopted.

Clause 76, dealing with the conditions under which corporate bodies could carry on the business of chemists and druggists, which had been left over to the last, occupied the final afternoon of the committee stage. An amendment was tabled proposing that the managing director of such companies should be a qualified chemist. This amendment, it was stated, had the support of the associated pharmaceutical societies in the Union. The Minister refused to accept this amendment, but on a non-party division it was carried by 60 votes to 44. The bill was reported with amendments and the report stage set down for an early date. Except for an amendment making it clear that the bill does not render unlawful any calling hitherto carried on lawfully in the Union, which may bring into the arena once again the supporters of the chiropractors, faith healers, and others of that ilk, which amendment will be dealt with at the report stage, it seems practically certain that the bill will at last find a place in the Statute Book this session.

#### Campaign Against Venereal Disease.

Under the auspices of the Women's Municipal Association a lecture on the prevention and treatment of venereal diseases was given to a large audience of women on January 17th. Councillor Mrs. Miriam Walsh, who presided, introducing the lecturer, Dr. Gavin O'Mally, venereologist to the City of Capetown, explained that the association, which was responsible for organizing the lecture, consisted of women who had combined to make Capetown a better and cleaner place. One of their objects was to make a special study of health problems in the city, and to this end they had decided to organize this meeting to rouse the public to the necessity of creating further facilities for the control of the disease, which was growing and spreading. There was need for more clinics, especially now that the previously separate municipality of Wynberg, a suburb of Capetown, had become a ward in the greater municipality. Wynberg was a large area and contained some of the very poorest parts of the peninsula. It was necessary to provide facilities in these poorer areas as in the other wards, and their object could be gained only if

the public would accord sympathy and support. Dr. O'Mally in his address described the nature of the two main types of venereal disease and the results they brought in their train. He emphasized the fact that the diseases were curable, and urged the necessity of immediate treatment. He summed up the weapons of attack under three heads: first, education, tending to a higher standard of knowledge, which would foster higher ideals in a community; secondly, better living conditions whereby the environment of the poorer classes might be improved; and thirdly, the establishment of free treatment centres. At the conclusion of Dr. O'Mally's lecture a film showing the effects of syphilis as an agent of family disruption was shown. Figures exhibited on the screen showed that during the period 1926-27, 1,942 patients had commenced treatment at the various clinics in the peninsula, and that 21,032 consultations had been given.

## Scotland.

### Vital Statistics, 1927.

THE REGISTRAR-GENERAL FOR SCOTLAND has issued a preliminary note on the vital statistics for 1927, which will be followed in due course by a full account in his seventy-third annual report. The most outstanding fact is a further fall in the birth rate, which has now reached 19.8 per 1,000, the lowest Scottish birth rate yet recorded. The birth rate was highest in 1876, when it was 35.6 per 1,000; that for 1927 is less by 44 per cent. The death rate of the year was 13.5 per 1,000, and the marriage rate 6.7, both below recent averages. The infantile mortality rate was 89 per 1,000 registered births, which was less than the mean of the preceding ten years. The death rate from all tuberculous diseases was 99 per 100,000, equal to the lowest yet recorded, and that from respiratory tuberculosis was 71 per 100,000, the lowest on record with one exception. Deaths from cancer (6,918) show a further increase. The Scottish birth rate for the fourth quarter of 1927 was 18.9 per 1,000; in the larger burghs the highest rates were in Coatbridge with 25.4, Glasgow with 21.5, and Hamilton with 21.3. Of the 23,282 children born 21,601, or 92.8 per cent., were legitimate. The deaths numbered 16,939, giving a quarterly death rate of 13.7 per 1,000; in the larger burghs the highest rates were 16.8 in Glasgow, 16.4 in Coatbridge, and 16.3 in Dundee. The Edinburgh rate was 15.5, and that of Aberdeen 13.0. In England and Wales the corresponding quarterly death rate was 11.7 per 1,000, which was 2.0 less than the Scottish figure. In Northern Ireland it was 13.7, as in Scotland. The infantile mortality rate was 100 per 1,000 registered births; the highest figures for the larger burghs were 167 per 1,000 in Coatbridge, 150 in Falkirk, and 147 in Paisley. The corresponding rates in England and Wales and Northern Ireland were 68 per 1,000 registered births, lower by 32 than the Scottish figure.

### Anderson College of Medicine, Glasgow.

The closing meeting of the Anderson College of Medicine at Glasgow for the session 1927-28 was held on March 15th. Emeritus Professor John Macintyre presided, and the prizes and medals were presented to the successful candidates by Dr. John D. Comrie, physician to the Royal Infirmary of Edinburgh, who subsequently gave a closing address upon the debt of modern medicine to the seventeenth and eighteenth centuries. The lecturer referred to the publication, three centuries ago, in 1628, of William Harvey's *Exercitatio Anatomica*, in which the circulation of the blood was demonstrated; it had come to be regarded as the most important single contribution which had ever been made to medical science. The Civil War in England had produced not only Harvey, but other great doctors, including Sydenham, who had the merit of introducing simple and rational methods of treating patients, and whose pre-eminence had been at the bedside, as Harvey's was in the laboratory. It had also produced Richard Wiseman, the "father of English surgery," who had spent some time in Scotland and contributed to the advance of

surgery there. The lecturer referred at some length to Peter Lowe, who had been trained in the wars in France, and who had settled in practice at Glasgow at the end of the sixteenth century; his *Discourse on the Whole Art of Chyrurgerie* was the first surgical book to be written by a Scotsman, and he had been responsible for the founding of the Faculty of Physicians and Surgeons of Glasgow. One of the latest surgical workers connected with the old College and the old Royal Infirmary in Glasgow two centuries after Wiseman's time had been Joseph Lister, who had there commenced in 1865 the experiments with carbolic acid which had contributed greatly to his fame. The lecturer believed that future generations would accord a still higher place for benefits conferred on surgery to Sir William Macewen, who had also worked in the Royal Infirmary and had been one of the earliest pioneers in aseptic surgery, which was now the routine of modern hospitals. Reference was also made to John Hunter, who had come from Long Calderwood, some eight miles south of the Clyde, and to William Cullen, who was born at Hamilton and who had been one of the most important early figures in the medical schools both of Glasgow and Edinburgh. The contributions of Glasgow to chemistry—notably that of Dr. Joseph Black, who had been the first to discover a gas, carbon dioxide—were also mentioned.

#### Larbert Colony Scheme for Mental Defectives.

Sir Alexander Graie presided over the sixty-seventh annual general meeting of the Royal Scottish National Institution at Larbert for Mental Defectives, in Edinburgh, on March 12th. The report showed that there were in the institution more than 500 mentally defective children, who were being trained for some useful work, so far as their capacities admitted. The directors were at present engaged in attempting to establish an industrial colony for 300 mental defectives, but had so far been able only to raise half of the £70,000 which was required. In the meantime, it was proposed to provide for 50 adult defectives by the erection of two villas, while Larbert House, the mansion on the estate which had been purchased for the establishment of the colony, had been converted into a home for the all-life care of 36 mental defectives, for whom fees could be charged. The latter home had been opened last July, and the proof that there was need for such accommodation was forthcoming in the fact that more than half of the places had been immediately applied for. In the medical superintendent's report it was stated that of the children admitted 9 were classed as feeble-minded, 34 as imbecile, and 9 as idiotic. It is pointed out in the report that no sharp line of demarcation between the definitely feeble-minded and the dull normal elements of the population can be drawn, nor between those who are regarded as merely feeble-minded and those who are definitely imbecile. It had been thought that the intelligence tests would enable definite distinctions to be made, but in practice this had proved impossible. Dr. R. D. Clarkson, medical superintendent, in submitting the report, said that it had formerly been imagined that feeble-minded children merely required a longer and slightly different education from others, but this idea had proved to be false; mental deficiency was an incurable condition, hence the decision of the directors to purchase an estate for the formation of an industrial colony. Many mental defectives could only be safe in such a colony. The chairman pointed out that satisfactory progress had been made with the colony scheme; a good lead had been given by the Council of the Women Citizens' Association, which had contributed more than £12,000. The directors felt that it was not only the duty of everyone to help in the matter, but that as individuals they should protect themselves from the menace which was constituted by the want of proper control of mental defectives. Lord Sands, in speaking of the increasing public interest in the whole-life care for the feeble-minded, said that in the old days when the greater part of the population was scattered over rural districts, the feeble-minded people contrived to live fairly happy lives, but these conditions had now almost entirely disappeared, and it was hardly possible for weak-minded and imbecile children to grow up in densely populated centres. Three great benefits were conferred by such

an institution: the removal of feeble-minded children from their homes and the streets, their training, and the ensuring of their happiness.

#### Debate on Animal Experiments.

A debate on the question whether vivisection was necessary or justifiable in the interests of mankind was held in the Y.M.C.A. Hall, Edinburgh, on March 16th. Mr. F. J. Robertson presided, and Dr. F. A. E. Crew of the animal research department in the University of Edinburgh supported vivisection, while the negative was maintained by Mr. Herbert Brown of Glasgow. Dr. Crew pointed out that experiments on animals were conducted for the definite purpose of seeking information which should give to mankind the power to control his physical environment as well as the life processes of animals and plants. He believed that the general public should know what scientists, who were paid by the State, were doing and how they did it. Stories of cats, agonized and suffering from artificially produced disease, had been spread abroad and embellished beyond all reason. He considered that anti-vivisection was largely taken up by elderly women through fanaticism, as it was rarely supported by men. He did not consider that these were the people who were best constituted to judge what was necessary or justifiable in the interests of mankind. No country could prevent the importation of the fruits of scientific investigation, although it might banish the investigator. He believed that animal experimentation was the only means available for securing certain knowledge, although it was only one of the many tools used by the scientist. After considerable discussion the motion that animal experimentation was necessary and justifiable in the interests of mankind was supported by a large majority.

## England and Wales.

#### Opening of the New Leeds Dental School and Hospital.

An event which has for long been eagerly awaited by all interested in the study of dentistry took place in Leeds when the new dental school and hospital was opened by the Speaker of the House of Commons, the Right Hon. J. H. Whitley. The Chancellor of the University, the Duke of Devonshire, who presided, was accompanied by the Vice-Chancellor and other representatives of the University, including Professor T. Wardrop Griffith, and by members of the staff of the Dental Hospital and of the General Infirmary. In his opening remarks the Chancellor emphasized the great importance of the connexion of the School of Dentistry with the University and with the General Infirmary at Leeds. Mr. Alexander Campbell, explaining how the cost had been met, said the Infirmary had given a site, which represented a contribution of £8,000; the Dental Board gave £5,000 towards the buildings and £1,500 towards equipment, and the members of the dental staff had shown the sincerity of their desire to have a properly equipped school and hospital by contributing over £2,000. The cost of the building and its equipment, apart from the value of the site, was just over £42,000. Sir Francis Dyke Acland also referred to the value of the close union which existed between the University, the General Infirmary, and the School of Dentistry, and pointed out that it was a good thing for the patients of a dental school, as it was for the patients of any teaching hospital, that there should be present a number of young men and women desirous of learning all that they could from the precept and example of their teachers. He added that the work of Mr. Whitley and that of a dentist had many things in common. In the hands of each there lay the full power to prevent the other man from talking; each had to listen entirely unmoved to protests against the use of the gag; each had to view with unruffled calm the expulsion of a stubborn member; and each had to be ready at the shortest notice to deal with any emergency with patience, coolness, and dexterity. The Speaker, in declaring the buildings open, described the event as another—and a very important—step in the development of the University of

Leeds, marking as it did the beginning of a great scheme for the provision of adequate accommodation for all its departments. He was confident that the disruption of the federal university, of which Manchester, Liverpool, and Leeds were the three constituent colleges, and the fact that Leeds had to stand by itself, would act as a spur to the people of Yorkshire. A description of the new buildings was given on January 14th (p. 72). Locally it is felt with pride that Leeds has now one of the best, if not actually the best, constructed and equipped dental hospitals in the country. Immediately after the opening ceremony a congregation of the University was held in the library of the Medical School. Honorary degrees were conferred by the Chancellor on the Speaker of the House of Commons, Mr. Charles Rippon, president-elect of the British Dental Association, Mr. W. Sinton Thorburn, warden of the school, and Mr. Walter Marston, chairman of the Clinical Dental Committee.

#### Research at Buxton.

The first research report of the Devonshire Hospital, Buxton, has lately been issued<sup>1</sup> under the joint editorship of Dr. C. W. Buckley, chairman of the Research Committee, and Mr. Joseph Race, biochemist to the hospital. The research laboratories of the hospital were established in 1912 to investigate the bacteriology of arthritis. In 1923 a research chemist was added to the staff and a laboratory equipped. At first the object was to study the chemistry of the Buxton mineral water and its action in the diseases for which it has had a reputation based upon empiricism since Roman times. The scope of the work has steadily widened to include the biochemistry of gout, acute rheumatism, fibrositis, and arthritis. The present report deals mainly with some of these problems. A paper by Dr. D. Macmillan, based on an Edinburgh M.D. thesis, presents the results of work on the calcium and carbonic acid content of the serum in chronic rheumatoid arthritis and other conditions. He shows that the calcium content of the serum presents no marked deviation from the normal in the rheumatoid group of diseases, and that, apart from infective arthritis, the carbon dioxide content of the serum also lies between normal limits. In the infective cases there is a slight but definite decrease. This worker has also shown that variations in the level of the calcium content of the serum may occur in an individual at different times, although the influence of the menstrual cycle on this calcium figure is negligible. A paper on acidophilous milk in infective arthritis by Dr. E. Biddle indicates that in a small group of patients such milk is a valuable agent in the treatment of chronic constipation and the conditions arising therefrom, but is of little value as a specific agent in the treatment of infective arthritis.

#### Antivenereal Measures in London.

In 1927, under the London County Council's scheme for dealing with venereal diseases, the number of days of treatment of in-patients was 112,413, as compared with 101,735 in 1926. The new patients who came to the aided hospitals under the scheme in 1927 numbered 28,965, of whom 18,801 were found to be venereal and 10,164 non-venereal. The figure of venereal cases is the highest since 1923, when it was 19,006. Of the total number of new cases, those of syphilis numbered 6,095; of gonorrhoea 12,496, and of soft chancre 210. The attendances numbered 767,278, as compared with 687,075 in 1926. The number of bacteriological specimens examined at the request of, and free of cost to, practitioners was 27,046, and 446 practitioners were on the approved list for the free supply of salvarsan or its substitutes. The arrangements are to be continued for another year, and grants amounting to £93,060 for treatment and pathological work and £5,350 for hostels are to be made, together with a further £8,025 in the event of certain additional facilities being provided. Certain neighbouring local authorities participate with London in the scheme, and, on the basis of user, 17 per cent. of the expenditure is met by them. The Government defrays 75 per cent. of the council's expenditure in carrying out approved arrangements.

## Ireland.

#### Ministry of Health for Northern Ireland.

SOME important correspondence has appeared recently in the local press on the subject of establishing a Ministry of Health for Northern Ireland. In the issue of March 16th of the *Belfast News-Letter* Dr. Kidd of Enniskillen detailed the arguments in its favour, and emphasized the point that the duty of the Minister was to prevent disease; such a function was too often overlooked, although it was of much greater value than that of attending to the treatment of illness when it developed. Though the question is complex it may be asserted with confidence that the general tenets of Dr. Kidd's letter will receive the cordial approval of the medical profession in Northern Ireland.

#### Public Health Organization in the Free State.

Dr. E. F. Stevenson, chief medical officer of the Department of Local Government and Public Health, in the course of a recent statement said that while efforts had been made to provide a water supply in urban districts in the Free State, the drainage was defective in many towns, and in some there was no sewerage system. Dr. Stevenson stated that the importance of good drainage in towns could not be overrated, and mentioned that in Dublin in 1904, when the main drainage scheme came into operation, the typhoid rate at once fell sharply. Defective drainage was the cause of diphtheria in parts of the counties of Cork and Limerick. The absence of a pure water supply and a proper sewerage system imposed heavy expensio on the community through preventable illness, and it was a short-sighted policy to try to save money on such essential requirements; this was especially true of tourist and holiday resorts, where the normal winter population was considerably increased during the holiday season, and sanitary arrangements should be based on the needs of the larger population. Progress in public health reforms was hampered by the neglect of local authorities to fix a suitable area of charge; to restrict the area to a few townlands was unwise. His department favoured the entire rural board of health area being made the area of charge for water supplies and sewerage. Dr. Stevenson said the main essentials in public health administration were sanitary areas of adequate extent and trained whole-time health officers to control sanitary inspection and administration. It was difficult to understand the hesitancy of local authorities to appoint whole-time officers of health when the cost in most country areas was but a fraction of 1d. in the £. Speaking of the progress made in this direction in the counties, Dr. Stevenson said it was slow but steady. The Rockefeller Foundation had promised generous financial assistance over a term of years towards the development of public health services in counties where county medical officers of health were appointed. Such public health services would come into operation during the present year in at least two counties, and schemes were being formulated for other counties which it was hoped to initiate at the beginning of next year.

#### Ulster Hospital for Women and Children, Belfast.

Professor Sinclair presided over the annual meeting of the Ulster Hospital for Women and Children on March 15th. The annual report showed that the average daily number of beds occupied was fifty-five, and the average annual cost per head was £78 19s.; 1,808 operations had been performed. The chairman, moving the adoption of the report, said that having been an active surgeon in the hospital at an early period of his career he had watched the development of the institution with particular interest and sympathy. The work of the hospital was extending and its efficiency was in no way impaired. He drew attention to the ante-natal clinic, and he hoped the subscribers would pay special attention to that department. On the motion of the Rt. Hon. Lord Justice Andrews a hearty vote of thanks was accorded to the medical and surgical staff and to the nursing staff for their services during the year.

## Correspondence.

### HISTORICAL EXHIBITION AT CARDIFF.

SIR,—The History of Medicine Section of the British Medical Association, with the assistance of the authorities of the National Museum of Wales, propose at the Annual Meeting of the Association this year at Cardiff to stage a series of exhibits illustrating the theory and practice of folk-medicine, human or animal, in the National Museum of Wales at Cardiff. To this exhibition the Librarian of the National Library of Wales has very kindly promised to send a series of books and manuscripts.

The council of the museum has placed the library room at the museum at the disposal of the Association for the purpose, and it is proposed that the exhibition should be open daily from July 20th to July 28th inclusive.

The object of this communication is to invite members of the Association, particularly those resident in Wales, who may either possess themselves, or be able to procure for the purpose of the exhibition, any objects relating to the theory and practice of folk-medicine, in connexion both with man and animals, to send them to Cardiff. It is thought that many practitioners in the country districts of Wales will, in the course of their professional work, have become acquainted with practices of this sort and be able to supply objects illustrative of such.

It is hardly necessary to stress the fact that practices of the character referred to have a very important ethnological and cultural bearing in addition to their purely medical aspects. Identical practices are widespread over Europe, and it is hoped, if an adequate response to our appeal be received, to institute during the week July 21st to 28th a series of lectures and demonstrations bearing on the exhibits which will greatly add to their interest.

Any communication should, in the first instance, be addressed to Dr. Strachan, 20, Windsor Place, Cardiff. Objects for exhibition may be sent in June or early in July, marked "B.M.A. Exhibits," to the Director, the National Museum, Cardiff. The name of the owner will be attached to each exhibit. All exhibits will be returned to the lenders in August.

Many objects of the character in question will be, of course, not in the possession of practitioners, but known by them to be in the houses of patients or others, and any assistance which can be given either by Sir Ewen Maclean or by Dr. Cyril Fox, the Director of the National Museum of Wales, in order to induce owners to lend such objects will gladly be given on request.—We are, etc.,

EWEN J. MACLEAN,  
President-Elect.  
GILBERT I. STRACHAN,  
Honorary General Secretary.  
H. R. FREDERICK,  
Honorary Secretary, Section of  
History of Medicine.

Cardiff, March 15th.

### PREVENTIVE VACCINATION OF THE NEW-BORN AGAINST TUBERCULOSIS.

SIR,—In your issue of March 3rd (p. 364) the results claimed by Professor Calmette for the B.C.G. vaccine are sorely criticized on the ground of statistics. Perhaps Wallgren may have changed his mind now that the latest figures are available for investigation.<sup>1</sup>

The argument that children supposed to have died of various maladies may in fact have died of tuberculosis does not stand before the following fact: The general death rate of children vaccinated with B.C.G., though exposed to contagion, is far lower than the death rate of non-vaccinated children, exposed or not to contamination.

This is not a question of academical interest, nor is it a tribute of admiration for Calmette's splendid work. The lives of many children are at stake. Can they be saved? These lines are meant to urge your readers to approach the question at its very source.—I am, etc.,

GUSTAVE MONOD, M.R.C.P.Lond.,  
M.D.Paris.

Vichy, March 10th.

<sup>1</sup> Premunition or Preventive Vaccination of the New-born against Tuberculosis, with the B.C.G. Statistics and Results from the 1st of July, 1924, unto the 1st of December, 1927. By A. Calmette. *Annales de l'Institut Pasteur*, January, 1928, vol. xlii, p. 1.

### MIDWIVES AND ANTE-NATAL WORK.

SIR,—The majority of obstetricians will agree with Professor McJhoy in her letter (March 17th, p. 466) with reference to ante-natal care. It is true that at a meeting recently I heard one man say that at the institution with which he was connected the ante-natal work was done, and well done, by midwives. It must be remembered, however, that the midwives attached to such an institution are the absolute pick of the nurses, and in no way represent the standard of efficiency among midwives as a whole.

It is very essential that the ante-natal care should be in the hands of qualified medical men, and the advice that I have given for some years past to students who are on the verge of qualifying and going into general practice is that they should put aside a certain hour every week for ante-natal examinations; further, that they should get in touch with the best midwives of the district, and persuade them to bring their own cases for examination on this particular day, and that they themselves should employ these midwives to conduct the actual labour in all the normal cases; moreover, that they should themselves see the patient again at the end of the puerperium. In this way they would know all about the patient in the event of any unforeseen emergency occurring during the labour, and they would know the final state of that patient.—I am, etc.,

London, W., March 19th.

MALCOLM DONALDSON.

### MINERS' NYSTAGMUS.

SIR,—In no one of the many letters and papers that have been written on this subject have I seen a satisfactory answer to the question: How does miners' nystagmus render a man incapable of hewing coal? We all know men with uncontrollable nystagmus (subjectively with a perpetual dancing of the objects viewed) who are hewing and have hewed coal for years as efficiently as their more fortunate companions who have not acquired the disease. I have seen many patients at the Eye Hospital who, although they had an uncontrollable nystagmus when standing erect in daylight, were still hewing without complaint; these were never giddy on stooping. Other patients become very giddy on stooping: they may reel after tying up their bootlaces, although no nystagmus can be seen in daylight and when erect; but it may be revealed at once if the room be darkened except for one point of light which they observe in a stooping position.

I am convinced that the incapacity for work in the pit varies directly as the giddiness on stooping. Of course, the giddiness may be due to other causes, such as arteriosclerosis, but if the patient shows nystagmus in a dark room and the other signs, such as the characteristic tremors, rapidity of pulse, etc., giddiness, sufficient to render him incapable of pit work, may be reasonably attributed to miners' nystagmus.

It would appear that this giddiness is a far more prevalent symptom than it was thirty years ago; I attribute this to the prolonged in-breeding of those predisposed to the disease in pit villages. As I have previously maintained, pit villages are hotbeds for the propagation of the disorder, or rather of the predisposition to the disorder, while coal hewing is the most exciting cause, as among 34,000 underground workers I found that the percentage of those who acquired the disease in one year was four times greater among the coal hewers than that among the other underground workers.

As the health of the patient is the main concern of our profession, it is our duty to urge every man who has miners' nystagmus to change his occupation if possible; but we, as referees, are asked whether the applicant through the disease is rendered incapable of earning full wages. The answer to this question rests entirely upon the signs, not the symptoms, of giddiness. As I have said before, it is quite impossible to assert that the applicant has not the disease after a single examination; the evidence of the disease varies so from day to day that an opinion based on one examination, in which the signs were not manifest, is unreliable.—I am, etc.,

Newcastle-upon-Tyne, March 17th.

A. S. PERCIVAL.

## DYSPHAGIA ASSOCIATED WITH ANAEMIA.

SIR,—I am glad to see from his letter in your issue of March 17th that such an experienced observer as Dr. William Hill agrees with me that the form of dysphagia described in the recent paper by Mr. A. Mason Jones and Mr. Robert W. Owen is not due to spasm. Dr. Brown Kelly's evidence in favour of spasm is very unconvincing; the sudden onset, for example, is just as easily explained by achalasia as by spasm.

I cannot agree with Dr. Brown Kelly that the closure of the lower end of the gullet is always firmer than normal in so-called cardiospasm, and that "sometimes it is so great that it yields only to prolonged steady pressure"; for anybody who has passed a mercury tube in such a case must have been struck by the remarkable absence of resistance offered by the sphincter, and by the absence of any grip upon it when it is withdrawn from the stomach. In exceptional cases temporary spasm may be present at first, but this is a result of the oesophagitis caused by irritation by retained food, and quickly disappears under treatment.

Though the old theory of cardiospasm is doubtless adopted in most books on oesophageal diseases, as Dr. Brown Kelly states, this is simply because they were written before Sir Humphry Rolleston's theory of inefficient relaxation was revived in 1915 by our clinical and radiological investigations, and subsequently confirmed by the pathological work of Stokes and Rake. Every physician and surgeon interested in disorders of the oesophagus with whom I have discussed the subject now accepts the theory of achalasia. Apart from the evidence afforded by the mercury tube and by the x-rays, the complete absence of hypertrophy of the cardiac sphincter—in striking contrast with the hypertrophy of the muscular coat of the rest of the oesophagus—is conclusive evidence that no long-continued spasm can have been present, as this would certainly give rise to hypertrophy.—I am, etc.,

ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, March 19th.

SIR,—In reference to the correspondence in the *Journal* under the above heading, it appears to me that the obviously easy passage of Dr. Hurst's large mercury-filled rubber tube not only knocks the bottom out of the cardiospasm theory of Mikulicz, adopted by Dr. Brown Kelly and others, but also excludes Dr. Hurst's own theory of achalasia in that portion of the gullet which lies between the level of the diaphragm and the cardiac orifice, as there is no evident abnormal resistance to the passage of the tube. Degenerative changes in Auerbach's plexus constitute an organic lesion, and this is more compatible with the view that there is feeble muscular activity and possibly a reduced reflex—that is, paresis—than with the theory of active contraction.

It seems to me that the dysphagias unassociated with a narrowing of the lumen at the lower end of the pharynx, which are under discussion, though not, of course, really analogous to those near the cardia, an area with unstriated muscle, have some points in common, more especially diminished contractile power and reduced reflex; moreover, in the pharyngeal case, the mercury tube passes without abnormal resistance, thus excluding spasm.

Dr. Hill's suggestion that the atrophic lesion in the lower pharynx in these feeble anaemic cases is in many respects similar to that observed in the paretic palate of chronic nasal catarrh would appear to be at least plausible, and not at variance with the clinical findings as far as I can see.

Although most of these atrophic pharyngeal cases improve under the stimulating massage effect of the passage of bougies, I have recently had a striking exception in my own practice, and am contemplating resort to electrical treatment on the assumption that the condition may be really paretic as suggested.—I am, etc.,

London, W., March 16th.

KENNETH A. LEES.

SIR,—It may be of interest, and perhaps of value, to summarize the findings in this laboratory in twelve cases of "pharyngo-oesophageal spasm."

Most of the patients came from Dr. Brown Kelly, and all were women of middle age. In one only was there

secondary anaemia; in none was there splenomegaly; in all there was a definite reduction in haemoglobin, a figure round 60 per cent. being commonly found. With the one exception the red cells were between 4 and 5 million, of normal size, shape, and staining (allowing for the deficiency in Hb), the leucocytes from 6,000 to 7,000 per c.mm. The organisms isolated from the pharynx were pneumococci or streptococci. The hydrogen-ion concentration of the saliva was examined and the limits of pH were from 6.4 to 6.6—that is, slightly on the acid side of normal.

The only constant blood change was therefore reduction in haemoglobin, and that is due, I think, to the restricted diet on which these patients live, anything which causes the slightest difficulty in swallowing—meat, for instance—being rigorously excluded.

The cause is probably to be found in the inflammatory changes of the mucosa and submucosa. The nerve terminations in the epithelium are affected; they may even be destroyed; and the swallowing reflex is not initiated—at least, it is not normally and instantly initiated. There is no intermuscular plexus within two centimetres of this region, and unless the pathological lesion is in the medulla, it is difficult to imagine how else the condition can arise; although in passing it may be noted that the sympathetic supply of the oesophagus is much more definite here than in the rest of its course.

As regards the analogous condition at the lower end of the oesophagus, it seems clear, from the results published from Guy's Hospital and here, that inflammatory changes in Auerbach's plexus are frequently associated with it. A lesion, however, on the mucosal side of the ganglia might produce exactly the same effects without the nerve cells showing any change at all. Indeed, as I have stated elsewhere, this may be the common sequence of events—that the lesion in and around the plexus is the result of the outward spread of a primary oesophagitis. In some cases there may be a specific selection of the ganglia by bacterial toxins, but these must be very uncommon.—I am, etc.,

J. A. M. CAMERON.

Victoria Infirmary, Glasgow, March 18th.

## GASTRIC SECRETION OF NEUTRAL CHLORIDE.

SIR,—The letter from my friend Dr. Poulton which appears in the *Journal* of March 17th (p. 469) may prove a little misleading if left without comment. It is essential to bear in mind that regurgitation of the duodenal contents and the secretion of a salt of chlorine by the stomach are two quite distinct issues; either may occur alone or both might occur together. To prove the occurrence of one does not disprove the occurrence of the other, and to prove that one gives only a partial explanation of the facts does not necessarily prove that its missing complement is to be supplied by the other. So that the fact that duodenal regurgitation does not by itself adequately explain all the facts is no proof whatever that the stomach normally secretes salt, as Dr. Poulton's letter seems to suggest. I have often said that if we might assume that both these things do occur this would probably provide the most convenient explanation of our problems; but unfortunately the convenience of an explanation is no guarantee of its correctness.

One other point is worth noting as it illustrates well the difficulties with which we are beset. Both the papers cited by Dr. Poulton are extremely interesting, and taken by themselves, apart from other work, they each make out quite a convincing tale; yet Dr. Poulton is very unfortunate in his choice of authorities, for while neither of them really supports the doctrine of gastric secretion of neutral chloride they are each mutually contradictory of the other in their conclusions. Baird, Campbell, and Fern (whose work has, I think, received too little attention) state definitely that "it is unlikely that chloride is secreted in the gastric juice in any large amounts," and one of their main conclusions is that at least in a proportion of cases the fall in the acid curve is due to neutralization by the alkaline pyloric secretion. Hansman, Day, and Clifton, on the other hand, do maintain that a salt of

<sup>1</sup> *Archives of Disease in Childhood*, 11, 12, p. 359; *Journal of Laryngology and Otology*, xliii, 3, p. 213.

chlorine passes through the stomach wall, but they are careful to avoid all mention of "secretion"; and the whole point of their paper is to show that the fall in the acid is brought about by dilution, and that neutralization only plays a minor role. Further, if Dr. Poulton accepts Dr. Campbell's curves from the duodenum he must dismiss as fallacious the assumptions on which the whole of Dr. Hansman's calculations are based. To avoid misconception I would add that I should be very glad indeed if Dr. Poulton, Professor MacLean, or anyone else can convince me that the stomach can normally secrete a salt of chlorine; but so far as I can see the evidence is still all the other way, and I know of no reason why Dr. Poulton should summon Pavlov to haul down his flag. I am, etc.,

London, W.14, March 17th.

GORDON W. GOODHART.

#### INJECTION TREATMENT OF VARICOSE VEINS.

SIR,—Dr. Borchers's communication on this subject in your issue of March 10th (p. 412) leads one to suppose that he regards syphilis as the common underlying cause of venous varicosity. In my experience there is not the slightest justification for such an assumption. On the other hand, the general use of salvarsan and its derivatives is fraught with danger, is very expensive, and, in the many non-syphilitic cases, quite useless.

Dr. Barber's letter on the same subject draws attention to the well-known experiment of injecting strontium bromide into a varicose vein and observing the centrifugal flow of the fluid. It should be pointed out, however, that the direction of flow depends upon the position of the limb. If it is horizontal the flow is centripetally directed. This raises the question as to whether it is not unsound practice to put patients with spontaneous phlebitis to bed. No doubt the specific gravity of the experimental fluids injected plays a part in the determination of the direction in which they shall flow. As I have pointed out in my monograph on the treatment of varicose veins, some of the injected fluid must pass centrally at once, as evidenced by the taste of quinine or the immediate tinnitus from salicylate.—I am, etc.,

March 13th.

A. H. DOUTHWAITE, M.D.

SIR,—It is evident from Dr. Borchers's letter that he considers the causation of all varicose veins to be syphilitic, and "from a pathological point the same as aneurysm." Therefore, he says, they should all be treated by injections of arsenical compounds, which, as he admits, do not cause thrombosis, but presumably act in a specific capacity.

It is possible to concede a certain percentage where syphilis is a factor, but I think, when one considers such other factors as pregnancy, increased intravenous pressure from uterine causes or constriction of the limb, long standing, and many other similar conditions, he is bound to assume the syphilitic percentage to be quite small. Accordingly, I cannot agree when Dr. Borchers says: "The great objection, in my opinion, to the use of other drugs which do not attack the cause of the disease, but produce thrombosis, is the risk of embolism . . ."; first, because I do not feel that he is attacking the cause of the disease by injecting arsenical compounds into quite the majority of varicose veins, and secondly, because I maintain that the risk of embolism after injection of solutions producing thrombosis has been proved to be negligible.

I shall be pleased to give Dr. Borchers references to over 30,000 injections in the literature to date, in which not one single case of embolism has been observed. In my own experience during the last three years of over 1,000 injections I have had such uniformly splendid results that I do not hesitate to express the opinion that, given great care in the technique of injecting sclerosing solutions, we have here a treatment which will supersede all other methods for the cure of varicose veins.—I am, etc.,

RONALD THORNHILL, M.B., Ch.B.

London, W.1, March 13th.

SIR,—With reference to Dr. Borchers's recommendation of "606" as an injection for varicose veins, it may be of interest to recount my solitary experience of this substance—or rather, neokharsivan—on a varix.

I was not using it to cure the varix, but for the treatment of syphilis in a woman in whom I found it difficult to obtain a suitable vein in the usual site, but who had a large and prominent varicose vein crossing the tibia on the left leg, apparently intended by Providence for my use. I gave her at least seven or eight of her twelve injections by this route, and can only state that the vein appeared just as large and varicose at the end of the treatment as it did before.

As to Dr. Barber's letter in the same issue, he apparently maintains that there is no risk of a clot from a thrombosed varix getting into the general circulation, and I confess I am puzzled. I have seen the statement made several times lately. If it refers only to the clot artificially induced in the injection treatment it is probably true, but I gather that it is intended to apply to all thrombosed varices. Is the teaching of the past on the subject, then, all wrong? And if so, what is the explanation of the sudden deaths which seem to have occurred with some frequency in this condition?—I am, etc.,

Portsmouth, March 13th.

E. W. DEWEY.

#### COLLECTIVE INVESTIGATION AND TUBERCULIN.

SIR,—I observe that Dr. Sharpe, writing from Hertford County Sanatorium, states in his letter in your issue of March 17th that he sees very few "simple, early, uncomplicated cases of [pulmonary] tuberculosis." This is a very important point. Where are these early cases which lie at the root of the whole matter? They are in the homes of the people—in the peculiar domain of the family doctor. While welcoming, therefore, investigation anywhere and everywhere, this particular research should be conducted locally, under the auspices of the Divisions of the Association. The tuberculosis dispensary would form a convenient centre if, as is to be expected, the authorities were sympathetically inclined, but it is essential that the active co-operation of those who are most favourably placed for diagnosing and treating the disease in its earliest stages should be retained.

I have purposely avoided the term "surgical tuberculosis" as unscientific. For purposes of demonstration visible lesions are obviously best; otherwise I do not discriminate between early pulmonary tuberculosis and early tuberculosis elsewhere; only let it be early. One of the great errors of tuberculin work hitherto has been to begin at the wrong end, with the advanced and unsatisfactory cases, which have resisted other forms of treatment, and in which tuberculin is tried as a last resort. This is a hopeless method. How would surgery stand such a test in relation to cancer? My experience is that in early pulmonary tuberculosis tuberculin is safe, easy, and effective when administered in accordance with Koch's methods, and with the limitations advised by him. It is to try out on a large scale Koch's momentous discovery that my suggestion has been put forward.

I have seen pulmonary tuberculosis flare up both with and without tuberculin, and although it is impossible to discuss individual cases without full details of the morbid condition and of the dosage of tuberculin, one may say, broadly speaking, that the earlier the case the less the risk. In the earliest cases there is none at all; it is mostly faulty technique which is responsible for the flaring up of suitable cases for tuberculin treatment which would not otherwise do so of their own accord. The point, however, is an important one and deserves close attention. Many years ago it was suggested by Sir William Watson Cheyne that secondary infection might play a mischievous part. Dosage and resistance vary, but there are clear leading indications to guide safely those who have knowledge and experience of the subject.

There is no difficulty in keeping careful records of pulse, temperature, weight, general, local, and focal reactions. I have taught many patients to do so, and have found

that the ordinary patient is a wonderfully acute observer in a matter which so vitally concerns himself.

I regard tuberculin as the key to the tuberculosis problem; at the same time I look forward, as Dr. Tippet does, to the possibilities of serum therapy. The question of the causal relationship of bovine to human tuberculosis is an important but separate question.

When the time comes for a central committee to be formed, one of its duties will be to consider the work which has already been done on tuberculin. In any such review the work of Dr. W. Camac Wilkinson, referred to by Dr. J. Gordon Hume, will fall to be carefully considered. There is a feeling that the investigation of Dr. Wilkinson's work by the committee of the Medical Research Council was not conducted with that sympathetic interest which it deserves.—I am, etc.,

Wandsworth, S.W.18, March 15th.

ROBERT CARSWELL.

SIR,—As a consistent advocate of the uses of tuberculin in general practice, and a convinced exponent of the value of tuberculin in the treatment of pulmonary tuberculosis from the very day of its discovery by Professor Koch, I challenge Dr. Sharpe to produce the protocols of the two cases upon which he ventures to suggest that tuberculin is a dangerous remedy for pulmonary tuberculosis. I wish to examine the evidence which has frightened him.

In a disease like pulmonary tuberculosis, liable to so many vicissitudes, vagaries, and uncanny complications, it is remarkable that out of many cases two might show fresh activity? Will Dr. Sharpe explain the meaning of the term "flare up"? The truth may be that these and other ill-defined disturbances, arising from the natural tendencies of pulmonary tuberculosis, are laid illogically to the charge of tuberculin. With my experience of thirty-seven years, in which I have consistently used tuberculin in doses that would terrify Dr. Sharpe, I have seen no evidence to indicate that the tuberculins mentioned by him (T.R. or B.E.), provided they are the preparations of Meister Lucius and Brüning, used in the proper cases, given in the proper doses, prepared by the physician himself on the spot and with a due regard to clinical manifestations, and injected at the proper intervals, will increase, for they will undoubtedly diminish, the inherent tendency to progress in this capricious disease. If Dr. Sharpe would visit the tuberculin dispensary I would show him scores and scores of charts proving that temporary increase of temperature, even with loss of weight and general disturbance, is almost invariably followed very soon by a distinct phase of improvement, and leads step by step, in the course of months, to the patient's recovery. As a set-off to his two cases, I will mention two cases which he can control for himself if he wishes.

1. A man, aged 28, developed pulmonary tuberculosis; he was in Brompton Hospital for four months, and then at Frimley for four months. From beginning to end the disease became worse and worse. He was discharged from Frimley, and was told that nothing more could be done. He went home, and was bedridden for six months, during which he wasted to a shadow. I was called in at this stage; and against my will consented to treat him with progressive doses of tuberculin. His pulse then was about 120; temperature 99.6° to 100° F. The physical signs were those of the third stage. From the first dose of tuberculin he began to mend. In twelve months he was able to leave his room, in another six months he was able to walk about. He has had tuberculin in enormous doses from time to time, and recently, at his own suggestion and with my consent, he applied to be taken back to a Government department, and his application was successful. It is now six years since I found him in this desperate condition after treatment at Brompton Hospital and Frimley. Dr. Sharpe can verify these facts from the patient, whose name I can give him in confidence with the patient's consent.

2. I was called in to see a patient suffering from pulmonary tuberculosis in the third stage, with pronounced disease of the larynx, causing hoarseness and pain on swallowing. There was disease of the vocal cords, with interarytenoid ulceration and oedema of both arytenoids. The patient, with my consent, was placed under the care of another practitioner, who, a month or so after I began treatment, told the patient that the tuberculin had made the condition worse. I suppose Dr. Sharpe would have said it caused the disease to "flare up." I wished to withdraw from this case, but the patient insisted that I should continue treatment with tuberculin without any interference. He was treated by me for several years, during 1911 and after, and subsequently did splendid work during the war, and is now (1928) apparently free from any symptoms of disease.

I have scores of cases in which I have observed exactly the same satisfactory results from the skilful, bold, and adequate use of properly prepared tuberculin.

Dr. Sharpe disagrees with the view that tuberculin can be given to ambulatory cases of open pulmonary tuberculosis with safety, success, and lasting results. What is his evidence? Let him produce it before any judicial tribunal and I will produce my evidence. My knowledge and experience of this disease lead me to believe that any casual "collective investigation" would be useless. The only investigation that is worth making must be on the lines I have already definitely laid down in the *British Medical Journal*.—I am, etc.,

London, W.1, March 17th. W. CAMAC WILKINSON.

SIR,—Your correspondents who have suggested collective investigation into the value of tuberculin appear to have forgotten the diversity of issues involved in such an investigation. Not only is there a great diversity in clinical conditions, but the aims of those employing tuberculin remedially; their choice of patient for the purpose, their views concerning dosage, spacing, and increase or otherwise of doses given, are equally diverse. Unless these varying circumstances are taken into account no useful conclusions can be drawn.

Some physicians aim at suppressing the tuberculin sensitivity of their patient by cumulative dosage, whereas others regard this as undesirable and sometimes dangerous. This alone results in enormous differences in dosage and mode of administration. Some control their treatment by temperature, pulse rate, and other clinical changes, including the state of the blood histologically and chemically, while others pay no attention to such indications. Even temperature records are differently compiled by different people; and are not always comparable. And clinically the same patient will react very differently to the same dose of tuberculin at different periods of his illness, and under different conditions of life and occupation.

It is eminently desirable that accurate investigations should be made into the action of tuberculin, but this can only be done in an institution where every factor can be noted and controlled.—I am, etc.,

Farnham, Surrey, March 19th.

F. R. WALTERS.

## PULMONARY TUBERCULOSIS: DIAGNOSIS AND TREATMENT.

SIR,—I should like to support Dr. F. G. Chandler's contention in your issue of March 17th (p. 469) that pulmonary tuberculosis is not soonest detected by physical signs.

As an instance, about nine months ago I saw a youth in whom pulmonary tuberculosis was diagnosed from the records of temperature and weight, general debility, and other symptoms, but in whom repeated examinations by auscultation, etc., gave no abnormal signs. The diagnosis was confirmed by sputum and x-ray examinations.

On the question of tuberculins raised by other correspondents in the same issue, I may say that this patient was treated with injections of diaplyte tuberculosis vaccine (Burnet's formula); he was kept at home for the first fortnight to observe the effect of the first few doses, but afterwards resumed his ordinary occupation—clerical work. He has made uninterrupted progress; there was a very slight general reaction after the first injection, but three days after his temperature became normal, and has remained so ever since; there have been no further reactions. He has gained weight steadily, is full of energy, and says he never felt so well before. A recent x-ray examination showed an almost entire absence of the former shadows, and there is no cough or sputum. Beyond ordinary hygienic measures no other treatment has been given. He has continued to live at home in comfort and carry on as a wage-earner instead of spending months in a sanatorium at some expense and discomfort.

The same vaccine has given results surpassing all expectations in other cases; in one, where the temperature had ranged from 100 to 102° F. for some weeks, it was brought to normal within fourteen days by the vaccine.

There is a very general distrust of tuberculins generally, and one hesitates to give rise to false hopes; but as this preparation appears to be a really specific antigen, which is free from unpleasant consequences, if given in small and gradually increasing doses, allows suitable cases to carry

on with their ordinary occupations, and does not require more supervision than can be given by the ordinary general practitioner, it seems worth further investigation.—I am, etc.,

London, N.W.8, March 18th.

E. CURNOW PLUMMER.

### SHOCK AND ABORTION.

SIR,—Dr. Hollins (March 17th, p. 471) seems to believe that shock associated with criminal abortion is due for the most part to the entry of irritating liquid into the peritoneum by way of the Fallopian tubes. To maintain his position he has to show that such shock is never produced in any other way—for example, by the simple dilatation of the internal os in the absence of anaesthesia; and, moreover, he has to explain the absence of early or immediate shock in cases of perforation of the intestinal canal. Gastric ulcer can perforate without causing shock; and a gangrenous appendix may give way with an apparent improvement of the patient, to the extent, indeed, that operation may be fatally postponed. Dr. Hollins has also to find a cause for "delayed" or ingravescent shock, so often unassociated with any peritonitis.

Truly it is difficult to understand how aberrant mental (emotional) states can cause profound bodily change; but that difficulty, I think, is largely due to the fact that though we admit or say that the "mind" (that is, the brain) affects the body, there seems no tangible demonstration of how it can do so or how it does so. In contemplating the causation of jaundice I was greatly impressed by the statement, admitted by Fagge and Pyc-Smith thirty-seven years ago, that emotion can cause jaundice.<sup>1</sup> It is, of course, easy to push such a statement aside, and, because we cannot see, or perhaps may never see, how emotion can have this effect, to deny the etiological relationship. Advance in medicine is not possible with such attitude: advance can only occur with the struggle to elucidate the *modus operandi* of such imputed cause. Repudiation can only be maintained when all possible explanations have been shown to be invalid.

As regards shock induced by criminal procedures, I indicated (in your issue of February 25th, p. 327) a mechanism causing shock which I think is sound. That all such procedures do not cause shock may possibly be explained by differences in the mentality of the patients: thus, some patients are more susceptible to pain than others. In any case, that aberrant mental (emotional) states predispose to shock, I think, is certain. Dr. Crookshank plainly is of this opinion (March 3rd, p. 375), and I have no doubt that others share the view.—I am, etc.,

Rugby, March 18th.

R. H. PARAMORE, F.R.C.S. Eng.

### HEALTH AND CHOICE OF A CAREER.

SIR,—During the last few years I have been impressed with the unsuitability of various trades and professions to the physique and general health of the individuals employed in them. This I attribute to the lack of consideration of the child's health in choosing a trade in which he should enter. Thus a youth employed in heavy manual labour and exposed to all types of weather may be found to possess a definite rheumatic tendency, possibly with a valvular lesion. In these cases some years may already have been spent in serving an apprenticeship to, say, the bricklaying or other outdoor trade, which may have to be discontinued, with the resultant loss of money to both boy and parents.

Again, a sedentary occupation, such as that of clerk, may have been chosen for a boy with a tendency towards tuberculosis, and whose family history in this respect is bad. Here again a judicious consideration of the boy's health before embarking him on a career would probably have led to the selection of some open-air occupation. I am convinced that much of the financial loss to the State caused through illness could be prevented by the medical man having some say in the mapping out of the child's future career.

My suggestion is that all children on attaining the age

<sup>1</sup> *Principles and Practice of Medicine*, 1891, II. 341.

of 13 or 14 years, and before leaving school, should be medically examined, and the school medical officer should advise as to the type of work most suited to the child's health and physique. For this purpose the various industries and professions might be classified into a number of groups according to the environment and manual or mental nature of the work, etc. While this would entail a little extra labour on the part of the medical officers inspecting the schools, it would be well justified by the great saving of suffering and taxation to the nation.

As medical practitioners we have all met the class of youth employed in some heavy manual trade who, after the first year or two of work, finds himself physically unable to carry on, and thus becomes a permanent burden upon unemployment or national health funds. Many of these cases of more or less total disablement might have been avoided if medical advice had been given at the commencement of the boy's career. This applies not merely to the heavy manual trades, but also to professions such as that of teaching, where examination on taking up a bursarship often discloses lesions which make teaching unsuitable for the individual. Here an examination at the age of 13 would probably have revealed the condition, or tendency to it, and led to the suggestion by the medical man of a more suitable career for the patient.—I am, etc.,

Penistone, Feb. 27th.

ALFRED A. MASSER, M.B., Ch.B.

### SHOCK IN BLACK RACES.

SIR,—The letter by Dr. George Sowden on shock after protrusion of intestines in your issue of December 31st, 1927 (p. 1250) contains the statement that "the resistance of the black races to surgical shock is considered to be very weak." I feel sure that an exactly opposite opinion has been formed by medical men who have had to do with the Bantu races (Kaffirs) in South Africa.

In an experience of over twenty years dealing with serious injuries resultant upon mining accidents I have invariably found that the Kaffir is peculiarly resistant to what we term surgical shock.

That the black man makes a good surgical but a bad medical patient is almost a truism. The explanation would appear to be that the black man endures the pain of trauma and post-traumatic shock in a manner comparable with that of the lower animals, but an illness is looked on by him as a visitation by a malevolent spirit, and as such admits of no explanation. Always a fatalist, the black man makes up his mind he is going to die, and die he does.—I am, etc.,

Rodepoort, Transvaal, Jan. 27th.

S. M. DICKSON, M.D.

## The Services.

### DEATHS IN THE SERVICES.

Colonel Cathcart Garner, C.M.G., C.B.E., R.A.M.C. (ret.), died at Southsea on February 5th, aged 66. He was born at Damfries on August 9th, 1861, the eldest son of the late William Hastings Garner of St. Grellans, Monkstown, county Dublin, and educated at St. Columba and at Trinity College, Dublin, where he graduated as B.A., M.B., B.Ch., and B.A.O. in 1885. Entering the R.A.M.C. as surgeon on July 28th, 1886, he became lieutenant-colonel after twenty years' service, and he retired on December 5th, 1906. On March 1st, 1896, he was seconded for civil employment in Egypt, and in that service he held the posts successively of president of the International Quarantine Board, Alexandria; deputy director-general of the Public Health Department, Cairo; and Under Secretary of State, Health Department, in the Ministry of the Interior. When war broke out in August, 1914, he rejoined the army and served in Gallipoli, Egypt, and Palestine, being A.D.M.S. in Palestine in 1917-19. He was mentioned in despatches in the *London Gazette* of January 28th, 1916, and received the C.M.G. and the C.B.E. in 1919. He was also a Knight of Grace of the Order of St. John of Jerusalem, an Officer of the Legion of Honour, and a Commander of the Order of George I of Greece. During his service in Egypt he received the Orders of the Medjidieh, second class, and Osmanieh, third class; and after the war the Order of the Nile. In 1900 he married Annetta Jane, younger daughter of the late J. Nadin, M.R.C.S. of Tipperary, and leaves one son.

## Obituary.

SIR DAVID FERRIER, M.A., M.D., F.R.S.,  
LL.D., D.Sc., F.R.C.P. LOND., Hon. F.R.C.P.I.,

Emeritus Professor of Neuropathology, King's College, London,  
and Consulting Physician to King's College Hospital and  
the National Hospital for the Paralysed and Epileptic.

We have to record with much regret the death of Sir David Ferrier, the great neurologist, on March 19th at his residence in Kensington.

David Ferrier was born on January 13th, 1843, at Aberdeen. He was educated at the University in that city, studying logic and philosophy under Bain, and graduated M.A. in 1863, securing a Double First. He then studied psychology in Heidelberg in 1864. His early medical education was obtained in Edinburgh, where he obtained first-class honours in the M.B. examination in 1868, and won the gold medal in the M.D. examination in 1870 with an elaborate thesis on the corpora quadrigemina. He was elected a Fellow of the Royal College of Physicians of London in 1877.

Equipped with such a wide mental training, Ferrier was essentially the man to interest himself in the problems of the physiology and pathology of the nervous system, and he became one of the pioneers of experimental research in this subject, bringing to his work the advantages of the practical knowledge of the physician. His earliest important publication was in the reports of the West Riding Asylum, where a pioneer school of neurology had been founded by Sir James Crichton-Brown in 1871. In the reports for 1873 Ferrier published his *Experimental Researches in Cerebral Physiology and Pathology*. This was followed by the Croonian Lectures in 1874 and 1875 on *Localization of Function in the Brain*, an event of fundamental importance in the history of neurological science. To appreciate the significance of Ferrier's researches it is necessary to recall the state of knowledge at that time in respect of cerebral localization. It was known by Galen that lesions on one side of the brain might cause paralysis on the opposite side of the body, and therefore some knowledge of localization of function in the brain already existed. Broca, in 1861, had described the association between lesions of the inferior frontal convolution on the left side with aphasia in right-handed persons, and in 1864 Hughlings Jackson had published his classical observations on the occurrence of localized convulsive movements (Jacksonian epilepsy) in association with lesions of the central convolutions of the brain. The earliest direct experimental evidence of motor localization was the work of the German physiologists Fritsch and Hitzig, in 1870. These observers were the first to show that the cerebral cortex in dogs was directly excitable by electrical stimuli, and that irritation of certain definite areas was followed by movements of particular parts of the opposite side of the body—movements which could be predicted from a knowledge of the point of stimulation. Ferrier was the first in this country to repeat and extend these experiments; he used the faradic current in preference to the galvanic, which was employed by Fritsch and Hitzig and

extended his observations to the monkey. He was followed later by Horsley, Schäfer, Bcevor, Sherrington, and others, who repeated the experiments in the higher apes and in man. Prior to these investigations it was believed that the surface of the brain was inexcitable by any form of external stimulus, and could only be activated by stimuli applied to the peripheral nerves and reaching the brain by central pathways. It was conceded that the cortex was concerned in some way with voluntary control of movements, but no knowledge existed of any localization of these phenomena, or that a special part of the cortex controlled the movement of particular groups of muscles. Such experimental study aroused bitter opposition from the opponents of vivisection. In later years the Research Defence Society was indebted to Ferrier, not only for practical substantiation of the claims of experimental medicine, but also for his help as treasurer.

Ferrier always acknowledged his indebtedness to the researches of Fritsch and Hitzig, and to the profound clinical and pathological observations of Hughlings Jackson. In his Goulstonian Lectures of 1878 on the localization of cerebral disease he brought his experimental work into line with the pathological findings in cases of cerebral disease in man. The second edition of *The Functions of the Brain* appeared in 1886. In addition to the localization of motor phenomena, the more difficult questions of the association of special parts of the brain with sensation and the special senses were the subject of prolonged investigation by Ferrier. A large part of his Croonian Lectures on cerebral localization in 1880 is concerned with the visual, auditory, and other sensory centres, and with the functions of the cerebellum. Though many of his conclusions in reference to these areas have been superseded, he laid the foundation of much of our present knowledge of the cortical representation of sensations; his pioneer work upon the cerebral control of movement has long passed the experimental stage, and forms the very basis of all modern neurological practice. That so much which is now everyday knowledge of fundamental importance was the fruit of the

Yours very sincerely  
David Ferrier

laborious researches of British physiologists and physicians is a source of legitimate pride to this country.

Other important contributions were the Harveian Oration in 1902 on *The Heart and Nervous System*, and the Lumleian Lectures in 1906 on *Tuberc Dorsalis*.

Many honours fell to Ferrier. He was elected a Fellow of the Royal Society in 1876, and was made a Laureate of the French Institute in 1878. He received the Marshall Hall Prize in 1883, the Baly Medal in 1887, the Royal Medal of the Royal Society in 1890, the Cameron Prize of the University of Edinburgh in 1891, and the Moxon Medal in 1912. His knighthood was conferred in 1911; he was made Hon. Sc.D. of Cambridge in 1914 and Hon. LL.D. of Birmingham in 1927. He was a member of the Council of the Neurological Society, on several occasions he held the post of vice-president, and he was president in 1894. He was one of the founders of *Brain*, which was started in April, 1878, the first editorial committee consisting, in addition to Ferrier, of Sir James Crichton-Browne, Sir John Bucknill, and Dr. Hughlings Jackson. For the first

five years of its publication the journal was edited in alternate years by Crichton-Browne and Ferrier. In 1913 Ferrier was president of the Medical Society of London, and of the Section of Neuro-pathology at the International Medical Congress held in London in that year. He was appointed lecturer on physiology at the Middlesex Hospital in 1870, and demonstrator of physiology to King's College Hospital in the following year; in 1872 he followed Dr. Guy in the chair of forensic medicine, and held this position until 1889, when he was elected the first professor of neuropathology.

Ferrier found time in his active life for practical interest in the British Medical Association, and was a member of the Metropolitan Counties Branch Council from 1888 to 1899. He was also a member of the old Scientific Grants Committee, now the Science Committee, and was President of the Section of Physiology at the Annual Meeting in London in 1895.

The funeral service was held on Thursday morning at St. George's Church, Hanover Square. It was attended, on behalf of the British Medical Association, by Dr. Alfred Cox, the Medical Secretary.

We are indebted to Dr. S. A. KINNIER WILSON for the following appreciation:

Sir David Ferrier was the last of the small and choice company of pioneers through whose labours the scientific neurology of to-day has come into being. Nearly sixty years have passed since he commenced researches on the functions of the central nervous system that brought him world-wide distinction and made his name familiar wherever neurology was taught. With those of Hughlings Jackson, Horsley, and Gowers, it will ever take that honoured position in the memorials of neurological science reserved by common consent for the path-makers and the masters. He was witness of the transition of knowledge of the nervous system and its diseases from the stage of empiricism and lucky guesses to its fruition in the fertile soil of accurate neuro-anatomy and experimentally proven neuro-physiology, and was himself one of the protagonists in this amazing revolution. The commonplaces of neural doctrine to-day were the discoveries of his early manhood, and we of a succeeding generation can appreciate but faintly the new world then revealed by the objective methods of precise cerebral experimentation. More than forty years separate us from the International Congress of 1881, when Ferrier gave a brilliant demonstration of the novelties of cerebral function and localization before the assembled savants of Europe; and fifteen years, too, have elapsed since their successors hailed him at the Congress of 1913 as the doyen of English neurology. If in these later times his work was less often referred to, if the echoes of old controversies had long since died away, if clinicians and surgeons cultivated the neurological field without a thought of the wilderness which it had replaced, a moment of quiet consideration would always bring to the mind of those who knew him and worked with or for him an impressive sense of the debt neurology owed to his imagination and to his persistence in following the path of minute and exact experimental research. Only a few of his friends are aware of the personal abuse which this line of investigation brought him, or of the extremes to which his opponents went in their endeavour to discredit his achievement.

It is on his many services to the experimental physiology of the nervous system that his reputation rests securely, nor can it be diminished by any contention that the technique was comparatively simple, and that the material lay ready to his hand and was only waiting to be utilized. Subsequent studies have not altered his conclusions fundamentally, even if the growing point of neurology has moved away somewhat from the rather schematic parallel he drew between excitation and response, between structure and function. To many of the younger generation he was known only as a clinician and clinical teacher, and this was possibly not the most original side of the man. A shrewd observer and a keen student of human nature, his contributions to clinical neurology are none the less by comparison not so memorable or so abundant. He had not Jackson's breadth of vision, or Gowers's faculty of patient and painstaking clinical scrutiny: what struck all those whose contact with him was of later

period was his mental vigilance and his consuming desire for information. Long after his best years had passed he was still a frequent attendant at meetings of the Neurological Section, the College, and the Royal Society, and within a few months of his death was still to be seen on occasion in the library of the Royal Society of Medicine. Nothing was more typical of Ferrier than this hunger for knowledge. On the day of Jackson's funeral in 1911 I walked away with him from the cemetery, and after many minutes of silence, occupied with his own thoughts of his teacher and friend, he suddenly turned and said, "Well, when I cease to take an interest in things it will be time for me to go." Those of us who were associated with him professionally and otherwise, who experienced his generosity, or who knew a little of that side of him that was but seldom revealed, will like to think of Sir David Ferrier as one whose life illustrated in perfection the meaning of the love of knowledge for its own sake, and who carried undimmed to the end the torch of science put into his hands sixty years before.

Dr. RAYMOND CRAWFORD writes:

The Editor has asked me to write a few words of Sir David Ferrier such as those who think of him only as a neurologist may perhaps leave unsaid. From an acquaintance of nearly forty years with him, first as my teacher and afterwards as my friend, I should pick out as most characteristic of the man two features—first, tireless activity of mind and body, and second, as a consequence of the first, the faculty of keen interest in everything that came under his notice. These qualities were appropriately tenants of a frail, brisk, dapper person, with a quick, springy step, and a face and eyes of penetrating keenness and alertness. He was a fine sample of that peculiarly Scotch product of combined graduation in honours in Arts and Medical Science, and was ready on occasion to improve a situation by an apt quotation from Horace. He always regretted that the exigencies of medical education compelled him to confine his clinic at King's College Hospital to neurological cases, and constantly urged me, when his house-physician, to show him cases of general medical interest. I recollect well his keenness to see the Widal reaction, newly introduced into clinical medicine, put to the test on the many typhoid patients that in those days thronged the wards; and when his turn came for a clinical lecture he would deliberately choose some subject outside his daily round of work, such as myxoedema, for his theme. On holiday, as at work, he retained the same boyish keenness on everything about him; he was never more happy than in the seaside cottage at Porthgwarra, where he spent many summer holidays, going to sea in all weathers in an open boat, and living the primitive life of the fisher-folk. In London one would often meet him at private views, and with a wide acquaintance in the world of artists he combined an appreciative knowledge of modern art.

After his retirement from practice his interest in medical science remained unabated. There was no more regular attendant than he at the lectures in the College of Physicians in recent years, and he loved to keep touch with the College that had bestowed on him all its highest honours and offices short of the Presidency, for he had been both Censor and Senior Censor, as well as holding several lectureships and gaining those prize medals bestowed only on men of the highest distinction.

One last tribute I desire to pay—a tribute to the indomitable determination with which, for the last two years of his life, he faced and fought the physical disability engendered by a very grave illness, such as most men would have accepted as a sentence of complete and final disability.

[The photograph reproduced is by Russell, London.]

SIDNEY MAYNARD SMITH, C.B., F.R.C.S.,  
Surgeon to St. Mary's Hospital, London.

We regret to announce the death of Mr. Maynard Smith, surgeon to St. Mary's Hospital, which took place at his residence in London on March 18th.

Sidney Maynard Smith was the son of the late Mr. W. H. Smith of the Admiralty, and was born in September, 1875. He was educated at Epsom College, and there obtained an entrance scholarship at St. Mary's Hospital Medical School.

After a distinguished career as a student he obtained the diplomas M.R.C.S.Eng., L.R.C.P.Lond. in 1898, and shortly afterwards was appointed house-surgeon to the late Mr. Edmund Owen. He served in the South African war as civil surgeon to the 3rd Battalion Welsh Regiment, and obtained the Queen's Medal and two clasps. On his return to London he was appointed house-surgeon to the Victoria Hospital for Children, and in 1902 became a Fellow of the Royal College of Surgeons of England. He graduated M.B.Lond. in 1904, and B.S. with honours in 1905; he then held the post of demonstrator of anatomy in St. Mary's Hospital Medical School. In 1904 he became surgical registrar to the hospital. He won a great reputation as a teacher, and in 1906 was appointed surgeon with charge of out-patients to St. Mary's Hospital and assistant surgeon to the Victoria Hospital for Children. He became surgeon to St. Mary's on the resignation of the late Mr. Ernest Lano in 1922.

Mr. Maynard Smith had a brilliant record of service during the great war. In 1914 he was appointed surgeon-in-chief to the St. John Ambulance Brigade Hospital, and, after devoting himself with the greatest energy to its organization and equipment, proceeded to France with this hospital early in 1915, holding the rank of honorary major in the R.A.M.C. At Etaples the St. John Hospital soon became famous for the outstanding perfection of its organization, and very many surgical cases were received; never was Mr. Maynard Smith's brilliant genius as an organizer shown to better effect than in the minutely detailed arrangements he made for dealing with the work of the St. John Hospital. His skill gained him a great reputation in France, and led to his appointment of consulting surgeon to the Fifth Army in 1916, with the rank of colonel, A.M.S. In his new position his work was equally successful, and he was largely responsible for the surgical arrangements for dealing with the heavy casualties of the prolonged battle of Passchendaele. He also distinguished himself greatly during the battle of St. Quentin and the retreat of the Fifth Army. He was subsequently appointed consulting surgeon to the Second Army, and held this post until the end of the war. For his services to the French Army during the fighting round Kemmel he was awarded the Croix de Guerre; for his war services he was three times mentioned in dispatches, and was created C.B. and a Knight of Grace of the Order of St. John of Jerusalem.

On his return from his long war service Mr. Maynard Smith resumed his busy practice in London and very heavy hospital work; in addition to his appointments at St. Mary's he was surgeon to the London Fever Hospital, consulting surgeon to the King Edward VII Memorial Hospital, Ealing, and consulting surgeon to Epsom College and the Royal Masonic Benevolent Institution for Girls. He was always intensely loyal to his old school, and served for some years with much enthusiasm as honorary secretary of the Old Epsomian Society. His contributions to surgical literature included the section on fractures of the lower extremity in the official medical history of the war. He was a former member of the Council of the Metropolitan Counties Branch of the British Medical Association, one of the secretaries of the Section of Diseases of Children when the Association held its Annual Meeting at Sheffield in 1908, and also one of the general secretaries of the special clinical and scientific meeting arranged by the Association in April, 1919.

As a surgeon Maynard Smith was distinguished by his shrewd judgement and the thoroughness of all his work; he was a splendid technician, neat and precise, and all his operations were performed after thoughtful preparation and with the most meticulous attention to details. He was a man of very charming personality, renowned among colleagues, patients, and students for his kindness and the distinguished courtesy of his manners. He was a delightful companion and a humorous after-dinner speaker. As in his other activities, he obtained distinction as a Freemason, being a Past Grand Deacon of the Grand Lodge of England. Maynard Smith had never been a man of robust health, but he did not allow this to limit his activities; his keenness for surgery impelled him to work harder even than the average London surgeon. Surgery

in general, and St. Mary's Hospital especially, have lost a very genial and kind-hearted man, and a surgeon of great distinction. As his war work showed, he had a genius for organization, and last year he was largely responsible for planning the details of the new theatre block at St. Mary's Hospital; it is sad that he should have passed away before its completion, but the hospital will for long reap the benefit of the time and thought he gave to the rebuilding. Mr. Maynard Smith married, in 1917, Isabel, daughter of Mr. F. I. Pitman, and the sympathy of his colleagues and numerous friends goes out to his widow and his son and daughter.

Major-General Sir S. G. Guise-Moore, K.C.B., writes: I should like to bear testimony to the loss both the medical profession and the army have sustained by the death of Sidney Maynard Smith. Late in February, 1918, Sir Anthony Bowlby, then senior consulting surgeon to the British Forces in France, informed me, as D.M.S., Second Army, that we were to have the services of Maynard Smith as consulting surgeon. His skill as a surgeon had preceded him, and was known by his work at the Duchess of Westminster's hospital at the base. The Second Army, like many another, had been fortunate in its consultants, both surgical and medical, and it did not take long to make certain that in "Maynard" it possessed, besides surgical prowess, a man of sterling qualities of heart and mind. At his own request he was early permitted to pay occasional visits to the front line, to regimental aid posts, and to advance and main dressing stations. He soon acquired a sound judgement as to what was essential to efficiency in the care, treatment, and evacuation of wounded. Anything short of this gave his gallant and kindly soul the deepest grief and concern. With any shortcoming he was never content until a remedy was found, and found it invariably was. At the casualty clearing stations, where his chief work necessarily lay, his cheery presence was always welcomed, his advice eagerly sought, and his capacity for unobtrusive and arduous labour recognized and appreciated. In the short intervals between the "crises" of incoming wounded, when alone it was possible to ponder and talk over things past and to come, we found in him a fund of quiet humour, a sense of timely loyalty, a gift of sage counsel, and a contentment that goes with successful accomplishment.

Dr. ALEXANDER HODGKINSON, who died in retirement at Farnham, Surrey, on January 6th, in his 82nd year, was a native of Salford, and received his early education at Queenwood College and Owens College, Manchester. He began his medical career as an apprentice and proceeded to the University of Edinburgh, where he graduated M.B., C.M. with honours, and B.Sc., being senior graduate, in 1873. He was a Baxter scholar in natural science, and afterwards pursued his studies at Vienna and Freiburg. Dr. Hodgkinson spent the greater part of his professional career in practice in Manchester, where he took an active part in medical affairs. He served as lecturer on diseases of the throat and nose at Owens College, was a corresponding member of the Société Française d'Otologie, Laryngologie and Rhinologie, and a member of various medical societies in Manchester. He was senior honorary consulting physician to the Manchester Hospital for Consumption and Diseases of the Throat, in the foundation of which he played a considerable part. In 1901 he attended the International Tuberculosis Congress in London, and in the following year was president of the Laryngological Section of the British Medical Association. Dr. Hodgkinson's interests extended far beyond the field of his profession. He travelled extensively in Australia and North and South America; among his hobbies were orchid growing, botany, physical optics, and photography, while his recreations included golf, fishing, and mountaineering. His wife died about a year ago, and he is survived by one son and two daughters.

Dr. JOHN ALLEN LYCETT, who died at Leamington on January 15th, in his 91st year, came of a medical family, being the third son of Dr. John Lycett, who spent the greater part of his career as a practitioner at

Minchinhampton; where he achieved more than local fame by his geological studies of the Cotswold Hills. John Allen-Lycett received his medical education at the Middlesex Hospital; in 1871 he obtained the diploma of M.R.C.S.Eng., L.R.C.P.Lond., and L.S.A. In 1881 he graduated M.D.St. Andrews, and a year later obtained the diploma of M.R.C.P.Ed. After holding various resident posts in the Middlesex Hospital Dr. Lycett commenced practice in Warwickshire in 1872, moving to Wolverhampton in 1874, where he built up an extensive practice in that town and the surrounding district, and remaining there until his retirement ten years ago, when he made his home in Leamington. He was, throughout his career, keenly interested in gynaecology, and played a considerable part in the establishment of the Wolverhampton and District Hospital for Women, serving subsequently on the staff of this institution as senior surgeon and consulting gynaecologist. He co-operated in the formation of the British Gynaecological Society, which was afterwards merged in the Royal Society of Medicine. He was a member of the Staffordshire Branch Council of the British Medical Association in the years 1888-91.

Dr. WILLIAM TIBBLES, who was born at Leicester in 1859, died suddenly at Nottingham in February. He received his medical education at Charing Cross Hospital, where he afterwards held an appointment as pathological assistant, and obtained the diplomas of L.S.A. and L.R.C.P.Ed. in 1881, and of M.R.C.S.Eng. in 1889. He had an extensive practice in Nottingham, and was medical officer of health for the Melton Mowbray rural district and a medical officer of the Nottingham District Union. From 1915 to 1919 Dr. Tibbles was assistant physician to the Nottingham General Hospital. He was a member of the American Association of Physicians and Surgeons, and of the Nottingham Medico-Chirurgical Society. He had long taken an interest in the work of the British Medical Association, serving on the Midland Branch Council in 1908-9 and again in 1921-22. He was the author of a number of books dealing with various aspects of dietetics, and his works on food attracted a considerable amount of notice during the war, both in Europe and in America. He had, at a much earlier period, been the recipient of academic honours in the United States in recognition of his studies in dietetics, including the honorary degrees of LL.D. (1895) and M.D. (1907) from the University of Chicago, and D.C.L. (1904) from the University of Washington. Dr. Tibbles was a prominent Freemason. His son has followed the family tradition and is also a member of the medical profession.

Dr. JOHN RAGLAN THOMAS, who died at Exeter on February 28th in his 73rd year, was educated at Epsom College, where he was Gilchrist scholar, and at St. Bartholomew's Hospital. He obtained the diplomas M.R.C.S.Eng. in 1876 and the L.S.A. in the following year. In 1884 he graduated M.B.Lond. with honours in midwifery and diseases of women, proceeding M.D. three years later; in 1886 he obtained the diploma D.P.H.Camb. After holding a resident post in St. Bartholomew's Hospital he succeeded, on the death of his father in 1877, to a large practice in Llanelli, but after about ten years in South Wales ill health compelled him to retire temporarily, and he spent some months recuperating in India. He then commenced practice in Exeter in partnership with the late Mr. A. J. Cumming; he also held the posts of Admiralty surgeon and certifying factory surgeon, and was a referee under the Workmen's Compensation Act. Dr. Thomas identified himself with the volunteer movement and the Territorial Force, from which he retired in 1912 with the rank of colonel, A.M.S. He was a vice-president of the Naval and Military Section of the British Medical Association in 1907. His services in connexion with the medical organization of the Wessex Territorial Division were recognized by his appointment as honorary physician to the King. He was a keen marksman and participated in numerous meetings at Wimbledon and Bisley, being a member of the team which won the China cup for Devon

in 1895. Golf was also among his recreations. He was greatly interested in literature and art, and himself produced many water-colour studies, notably of the coast near Exeter.

## Medico-Legal.

### A JURY'S VERDICT CRITICIZED.

*Tyndall v. Alcock.*

MEMBERS of the medical profession will certainly endorse the *obiter dictum* of Lord Justice Scrutton that a jury is rarely a suitable tribunal to try a case which involves a right differentiation between what is an error of judgement—which is not actionable—and what is, in fact, a departure from the degree of skill which a professional man holds himself out to exercise—which constitutes negligence in the eyes of the law. Even so, it must be poor consolation to Dr. Arnold Alcock of Gloucester to know that, although the Court of Appeal, consisting of Lords Justice Scrutton and Sankey and Mr. Justice Romer, might have come to a different conclusion from that of a special jury at Bristol Autumn Assizes, yet the sacrosanct nature of a jury's findings of fact prevented the Court of Appeal from interfering with their verdict.

A report of the case as it was presented at the assizes appeared in our issue of December 10th, 1927, at page 1121. Briefly, a child named Phyllis Tyndall, aged 10, who was described as "a prodigy at the piano," fractured her left humerus as the result of a fall from a pony. Dr. Alcock claimed to have skilfully adopted the most approved scientific method in reducing the fracture, since during the operation he caused an x-ray photograph to be thrown upon the screen, and when he had finished his task the radiologist reported that the bones appeared to be in perfect alignment. Unfortunately, however, the child's arm became fixed at the elbow and Volkman's contracture developed, resulting in impairment of movement. The trial jury found that Dr. Alcock had been negligent, and proceeded to apportion £2,000 damages to the child and £150 to the mother.

The comments of the three members of the Court of Appeal upon this verdict are interesting. While Lord Justice Sankey agreed with Lord Justice Scrutton that questions of professional negligence were difficult, he thought an ordinary jury was more likely to come to a correct conclusion than a jury of experts; Mr. Justice Romer ironically observed, however, that Dr. Alcock must get such consolation as he could out of the fact that trial by jury was the foundation of his liberties!

Questions of fact are the peculiar province of a jury, and it is an axiom firmly established in our law that a jury's verdict cannot be set aside unless it can be said that there was no evidence upon which they could have found their verdict. As Lord Justice Scrutton tersely observed, the jury were the persons put there by the Constitution to try actions involving questions of negligence, and, since there was evidence before them on which they were entitled to decide either way, it was impossible for a Court of Appeal to interfere with the result, although such a court might have come to a different conclusion. The verdict of the constitutional tribunal was, therefore, allowed to stand, and Dr. Alcock's appeal was dismissed.

### REGISTRATION OF DANGEROUS DRUG PURCHASES.

The West London magistrate (Mr. Marshall), on March 18th, imposed a fine of twenty-one guineas and three guineas costs on Dr. F. D. Parbury of West Kensington, who was charged with failing to enter in the register required to be kept for that purpose certain purchases of dangerous drugs.

Mr. Vincent Evans, who represented the Director of Public Prosecutions, said that Detective-Inspector Burnby interviewed the defendant regarding certain prescriptions of heroin and the cocaine which he had supplied to two women patients. The inspector asked to see his register of purchases of dangerous drugs, and he produced a book which contained a list of prescriptions, but no particulars of purchases of dangerous drugs, although on October 31st and January 1st he had made purchases from wholesale chemists of morphine sulphate and diamorphine from hydrochlorate. The Home Office regarded this kind of offence as serious, as it was most essential that the sources of all dangerous drugs should be easily traceable.

Mr. F. Denny, for Dr. Parbury, said that he had, until 1926, practised for fourteen years in Jersey, and was not cognizant of the regulations respecting dangerous drugs in this country. There was no suggestion that he had been engaging in any illicit dealing in drugs, and at most he had been guilty of great carelessness and stupidity.

## COUNCIL ELECTION.

MONDAY, March 19th, was the last day on which the names of candidates were to be received for the election of Members of the Council, which will take place on July 5th. Twelve nominations have been forwarded to the Secretary by candidates seeking to fill the four vacancies occasioned by the retirement in rotation of Sir Anthony A. Bowlby, Sir D'Arcy Power, and Mr. F. J. Steward (Vice-President), and by the death of Mr. W. Thelwall Thomas, M.B.E.\*

The candidates are: Mr. F. J. Steward (Guy's), Member, 1895, Fellow 1898; Mr. L. P. Gamgee (Birmingham), Member 1891, Fellow 1894; Mr. R. G. Hogarth (Nottingham), Member 1891, Fellow 1894; Mr. T. P. Legg, C.M.G. (King's College Hospital), Member 1895, Fellow 1897; Mr. H. W. Carson (Prince of Wales's), Member 1895, Fellow 1899; Mr. J. P. Lockhart-Mummery (St. Mark's), Member 1899, Fellow 1900; Mr. Russell J. Howard, C.B.E. (London), Member and Fellow 1903; Sir Crisp English K.C.M.G. (St. George's), Member 1903, Fellow 1905; Mr. Harold W. Wilson (St. Bartholomew's), Member 1903, Fellow 1905; Mr. C. Choyce, C.M.G., C.B.E. (University College Hospital), Member and Fellow 1905; Mr. R. E. Kelly, C.B. (Liverpool), Member and Fellow 1905; Mr. Robert Milne (London), Member 1904, Fellow 1905.

The constitution of the Council since July, 1927, has been as follows:

*President.*—Sir Berkeley Moynihan, Bt., K.C.M.G., C.B., Council (1) 1912 (substitute), (2) 1919, Pres. 1923.

*Vice-Presidents.*—Sir Cuthbert S. Wallace, K.C.M.G., C.B., C. (1) 1919, (2) 1927; Mr. F. J. Steward, C. 1927.

*Other Members of Council.*—Sir Anthony A. Bowlby, Bt., K.C.B., K.C.M.G., R.C.V.O., C. (1) 1924, (2) 1921, (3) 1920, Pres. 1920, 1921, 1922; Sir D'Arcy Power, K.B.E., C. (1) 1912, (2) 1920; Sir H. J. Verrier, C. (1) 1913, (2) 1921; Sir John ... M.G., C. (1) 1918 (substitute), (2) 1925; Mr. W. Thelwall Thomas, M.B.E. (died after second meeting (Rowlands, O.B.E., C. 1921).

*Members of Council.*—Sir James Berry, C. 1923; Mr. J. Herbert Fisher, C. 1923; Mr. W. Sampson Handley, C. 1923 (substitute); Sir Percy Sargent, C.M.G., D.S.O., C. 1923 (substitute); Mr. G. E. Gask, C.M.G., D.S.O., C. 1923; Mr. W. McAdam Eccles, C. (1) 1914, (2) 1924; Mr. Wilfred Trotter, C. 1924; Sir Charles Gordon-Watson, K.B.E., C.M.G., C. 1921; Mr. A. H. Burgess, C. 1925; Mr. V. Warren Low, C.B., C. (1) 1916 (substitute), (2) 1917, (3) 1926 (substitute); Mr. Victor ... C. 1925 (substitute); Mr. G. Grey Turner, C. 1926; Mr. Hugh Lett, C.B.E., C. 1927 (substitute).

The medical schools are represented as follows:

## London:

*St. Bartholomew's ...	6
Guy's ...	3
London ...	1
St. Mary's ...	1
Middlesex ...	2
St. Thomas's ...	3
University College Hospital ...	1
Royal Free ...	1
Total London ...	18

## Provincial:

Bristol ...	1
Cardiff ...	1
Leeds ...	1
Liverpool ...	1
Manchester ...	1
Newcastle ...	1
Total Provincial ...	6
Total Council ...	24

\* Two Members retire and do not seek re-election.  
† Died in September, 1927.

## UNIVERSITY OF OXFORD.

The Master and Fellows of University College announce the election of P. C. Mallam, M.A., B.M., B.Ch., Queen's College, to a Radcliffe Travelling Fellowship. The Fellowship is of the value of £300, and is tenable for two years, during fifteen months of which the holder must engage in foreign travel and study. Mr. Mallam was formerly President of the Oxford University Boat Club, and was subsequently a student and resident at St. Mary's Hospital, London.

C. W. Carter, B.M. (Fellow of Queen's), has been appointed University demonstrator in biochemistry, and C. G. Douglas, D.M. (Fellow of St. John's), has been reappointed University demonstrator in general metabolism.

## UNIVERSITY OF SHEFFIELD.

At a congregation held on March 15th the degrees of M.B. and Ch.B. were conferred on P. B. Lee-Potter.

## UNIVERSITY OF DUBLIN.

The conferment of the honorary degree of M.Ch. upon Sir John Bland-Sutton, Bt., LL.D., F.R.C.S., has been approved by the Senate of the University on the recommendation of the Board of Trinity College. The honorary degree of M.A. is to be conferred on Miss Margaret Huxley, matron of the Elpis Nursing Home.

## TRINITY COLLEGE, DUBLIN.

At the spring commencement of Hilary term, held on March 16th, the following degrees in the Faculty of Medicine were conferred:

M.B., B.Ch., B.A.O.—L. R. Brumberg, D. M'M. Carson, G. Q. Chance, A. C. C. Charles, W. Crawford, A. R. Ewart, A. G. C. Ffolliott, J. R. Hanna, O. R. Harris, H. E. Knott, Christina McDonald, A. A. Morgan, C. E. G. Nunn, Wilfred D. C. T. Pigott, F. G. Stewart, C. Watson, J. E. Wells.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons this week passed the Navy, Army, and Air Force Estimates through the report stage. It also discussed the "Zinovieff letter" and a bill introduced from the Labour party dealing with the coal-mining industry. A Public House Improvement Bill, "to amend the law relating to the sale by retail of excisable liquors," was presented by Dr. Fremantle on March 15th, and was read a first time.

Dr. Fremantle was in the chair at a meeting of the Conservative Health and Housing Committee at the House of Commons on March 13th, at which Mr. E. D. LIDBETTER, relieving officer of Bethnal Green, and a member of the Eugenics Education Society, gave an address. Mr. Lidbetter produced records of pauper families going back in some instances for 150 years, which, he said, pointed, not to a general degeneracy of the population, but to the inbreeding of degenerates in "pockets." He remarked that sterilization of the unfit would not meet the case of the apparently fit person with an ancestry such as he had cited, but in his view there was scientifically no difference between sterilization and segregation. Asked about the experience of California with sterilization of the unfit, Mr. Lidbetter said it was reported to have been successful there. Members of the committee pointed out that the Mental Deficiency Act in this country provided not only for segregation, but for guardianship, and that three-fifths of the mentally defective in this country were covered by one or the other. Mr. Lidbetter answered that he did not think highly of the guardianship system. The forty members who attended the meeting were much interested in the discussion. Several offered to assist the Eugenics Education Society, and Dr. Fremantle was asked to represent to the Ministers concerned that there was a strong case for a Government grant in aid of research into the subject and towards the cost of publishing results.

## National Health Insurance.

Mr. CHAMBERLAIN, answering Mr. Rhys Davies on March 15th, said no approved society had been compelled through lack of funds to abandon the whole scheme of additional benefits. About a hundred societies, covering a total membership of between three and four million insured persons, which included dental and ophthalmic benefits in their schemes, had found that the demand for those benefits amongst their members had so far exceeded the expectation that the amounts allocated to the benefits for a particular year had been exhausted before the end of that year. They had consequently been obliged to defer the authorization of claims until the beginning of the following year, when further money became available. In nearly every case the authorization of claims for benefits had been resumed. Sir HENRY CAULEY asked if the balances of the societies would be improved if the doctors were able to exercise independent judgement on men continuing on the panel or coming off it. No answer was given.

Answering a question about dental treatment of insured persons, which Mr. Rhys Davies put on March 15th, Mr. CHAMBERLAIN said it would be improper for a society to require a member to attend for treatment at a dental clinic if he would prefer to obtain treatment elsewhere. He promised to look into any case where approved societies imposed the condition that members must attend dental clinics during working hours. Mr. RHYNS DAVIES asked whether the Minister was aware that some societies had established separate institutions and were giving dental treatment through clinics to their members, making it a condition that dental treatment could not be provided elsewhere. Mr. CHAMBERLAIN asked for particulars of any case where choice of dental treatment had been refused. Mr. EDMUND WOON asked whether the Minister intended to set up dental clinics under the National Health Insurance Bill. Mr. CHAMBERLAIN replied that approved societies were not at present empowered to establish dental clinics, but some societies were of opinion that in large industrial centres the setting up of dental clinics might be attended with advantages. The question had been fully considered by the Dental Benefit Joint Committee, composed equally of representatives of the dental profession and of approved societies of all types, and that committee recommended that to test this form of treatment one or more experimental clinics should be set up. Under the National Health Insurance Bill now before the House provision had been included which would enable this to be done, subject to regulations to be laid before Parliament. There was, however, no intention of making it compulsory for any insured person to obtain his treatment in a clinic if he would prefer to be treated by a private practitioner. Mr. Chamberlain added that he was satisfied that freedom of choice of dentist must be retained. There were no specially established dental clinics.

Answering Dr. Vernon Davies, on March 15th, Mr. CHAMBERLAIN said he knew some employers did not allow women employees to

remains at work in advanced pregnancy. Any such rule of an employer did not entitle an insured woman to sickness benefit under the National Health Insurance Act, but if she could produce medical evidence to the satisfaction of her approved society that she was incapable of work, she would be entitled to benefit. Dr. DAVIES asked if Mr. Chamberlain knew this question caused great difficulty to medical officers, doctors, and approved societies, and whether he could include this class of case in the National Health Insurance Bill. Mr. CHAMBERLAIN said there was a later question on the paper regarding that.

On March 19th Sir KINGSLEY WOOD informed Mr. R. Morrison that the Minister of Health had not recently issued any regulations which authorized panel doctors to charge insured persons over 65 the sum of 1s. for medical certificates. There was no power under the Acts to fix a fee for certificates which were not required for National Health Insurance purposes. Mr. Morrison asked whether insured persons over 65 who were not entitled to cash pensions were still entitled to medical advice, and whether that medical advice included medical service if required. Sir KINGSLEY WOOD replied that, as his answer implied, a charge other than that authorized under the National Insurance Act was not a proper charge.

#### Maternal and Infantile Mortality.

Mr. Chamberlain has received the resolution regarding maternal mortality passed on February 28th at a meeting of 600 representatives of local authorities and friendly societies. He is taking action to give effect to the recommendations made by the report recently issued by the Ministry of Health on protection of motherhood in regard to medical inquiry into all deaths due to childbirth, further training and experience in midwifery as a preliminary to general practice in medicine, the appointment of an official committee to advise on the whole question of the training and employment of midwives, and action to induce local authorities to make their maternal services adequate.

Sir KINGSLEY WOOD told Sir Robert Thomas, on March 14th, that the Annovored Societies Consultative Council has referred to a special subcommittee the proposal to modify maternity benefit so as to provide medical and nursing services in addition to a cash payment, linking up such services with the maternity and child welfare work of local authorities. Mr. Chamberlain will give the report most careful consideration as soon as he receives it.

Answering Major ROPNER, on March 14th, Sir KINGSLEY WOOD said the infant mortality figures for Houghton-le-Spring and Chester-le-Street during 1927 showed a small increase in each district compared with 1926, although the rates were lower than for 1924 and 1925. Only the report of the medical officer of health for Houghton-le-Spring, which was written on February 22nd, 1928, suggested under-nourishment as one cause of the increase. Other medical officers in the county of Durham attributed to the exceptional prevalence of bronchitis and pneumonia the temporary increase of infant mortality in that county during the last few months. Mr. LAWSON asked whether the Ministry of Health accepted only death from starvation as proof of destitution. Sir KINGSLEY WOOD denied this. Mr. MONTAGUE asked whether a medical officer's report stated that the deaths from bronchitis showed that there was lack of clothing as well as of food. Sir KINGSLEY WOOD said he was not aware of that.

In a reply to Mr. Robert Richardson, on March 15th, Mr. CHAMBERLAIN said that for the quarter ended December, 1927, the infant mortality rate for the urban district of Houghton-le-Spring was 152, and not, as stated by Mr. Richardson, 210 per 1,000. No official figures were available in this district for separate months. Mr. RICHARDSON alleged that the rate in October was 300 and in January, 1928, 210, but Mr. CHAMBERLAIN remarked that in a district with so small a population very slight variations in the numbers of births or of infantile deaths resulted in such substantial differences in the monthly infantile mortality rate as to render it of little value for purposes of comparison. The addition of one death meant an addition of 50 per 1,000 in the mortality rate. Mr. RICHARDSON, in a supplementary question, asked whether Mr. Chamberlain did not know that the medical officer of health had given the figures from October until February, showing little or no diminution, that he said it was the highest death rate ever recorded in Houghton-le-Spring, and that he was certain it was because of the underfeeding of mothers and children. Mr. CHAMBERLAIN said that was merely a repetition of the question.

#### Small-pox.

On March 20th Mr. CHAMBERLAIN gave Mr. Groves a detailed statement showing the number of small-pox cases and deaths from that disease which occurred in London in the five years 1923 to 1927, with the age, sex, place of death, and vaccinal condition of each case. The statement showed that in 1923 there were 13 cases of the disease, as follows: male, 12 years of age, unvaccinated; male, 15, vaccinated in infancy (a port sanitary case); female, 23, vaccinated in infancy; female, 23, unvaccinated; two females, 28 and 30, both vaccinated in infancy; male, 31, vaccinated in infancy (it was stated that this patient had been revaccinated in 1914, but the available evidence did not appear to support this statement); male, 47, and female, 44, both vaccinated in infancy; male, 50, unvaccinated; male, 53, vaccinated in infancy (this case was fatal, the patient dying in Joyce Green Hospital, Dartford); female, 79, vaccinal condition doubtful; male, 32, probably twice vaccinated, poor scars (port sanitary case). In 1924 there were 4 cases, as follows: male, 24, vaccinal condition doubtful; female, 54, and male, 54, both vaccinated in infancy; female, 73, vaccinal condition doubtful.

In 1925 there were 14 cases, as follows: females, 2 years and 4 years, both unvaccinated; female, 17, unvaccinated; male, 24, vaccinated in infancy (port sanitary case); male, 25, unvaccinated

(port sanitary case; this case was fatal, the patient dying in the Port of London Hospital, Denton); male, 27, vaccinated in infancy (port sanitary case); male, 30, vaccinated in infancy; female, 31, vaccinated in infancy; male, 44, vaccinated in infancy; and in 20 years of age (port sanitary case); male, 47, and female, 49, both vaccinated in infancy; male, 57, vaccinated in infancy; female, 57, vaccinated in infancy (fatal case, died in Long Reach Hospital, Dartford); male, 66, vaccinated in infancy.

There were 8 cases in 1926, as follows: male, 14, unvaccinated; male, 23, vaccinated in infancy (port sanitary case); female, 32, vaccinated in infancy; male, 34, vaccinated in infancy and at 10 years of age (port sanitary case); male, 36, vaccinated in infancy (port sanitary case); female, 42, vaccinated in infancy (fatal case, died in Long Reach Hospital, Dartford); females, 52 and 64, both vaccinated in infancy.

In 1927 there were 7 cases, as follows: male, 4 years, unvaccinated (fatal case, died in Long Reach Hospital, Dartford); male, 20, unvaccinated (port sanitary case); male, 25, vaccinal condition doubtful (port sanitary case); males, 29 and 33, both unvaccinated; female, 41, unvaccinated (fatal case, died in Joyce Green Hospital, Dartford); male, 54, vaccinated in infancy.

#### Foot-and-Mouth Disease.

In the House of Lords, on March 20th, Lord ERMLE asked whether the existence of two distinct types of foot-and-mouth disease was confirmed by the Research Committee. He further asked if the type of disease most prevalent in Denmark, Holland, and Belgium was the same as that which mainly prevailed in this country, and if the virus had been recovered from any imported supplies of chilled or frozen meat. Viscount HALDANE said the Government ought to search the biological laboratories and the universities to find a comparatively young man to devote himself exclusively to research into the bacillus of the disease. The Earl of STRATHMORE, replying for the Government, said that if the Government could find anyone to devote his services to this work his services would be employed. The Research Committee had confirmed the opinion arrived at by the Veterinary College in Paris, that there were two strains of foot-and-mouth disease, and that, if animals became immune after being attacked by one strain they were not thereby prevented from attack by the other. Those facts made it difficult to eradicate the disease, and the only way they saw at present was by slaughtering infected animals. There was no information on the type of the disease in the Argentine, but it was very prevalent. The Government hoped that the steps the Argentine Government had promised to take to check the sending to this country of carcasses likely to be infected would prove effective. No attempt had been made by the Research Committee to recover the virus from imported supplies of chilled or frozen meat, because it was felt that the task was impracticable. So many carcasses were imported that although they might take carcass after carcass and find nothing, yet all the time disease might be brought in. Lord BLESSING suggested that something might be done to co-operate in the matter of research with the eminent experts who were working in the Argentine and Brazil.

#### Edinburgh Corporation Bill (Venereal Diseases).

On March 15th Sir John Gilmour and Mr. Chamberlain received a deputation representing the Corporation of Edinburgh, and consisting of the town clerk, the medical officer of health, and the venereal diseases officer of that city, who set before these Ministers the facts which had induced the Corporation of Edinburgh to ask, in the Edinburgh Corporation Bill, for greater powers of detecting, controlling, and curing venereal disease. The speech of the town clerk was particularly impressive in its citation of the damage done by lapses or recalcitrant cases, but the Secretary for Scotland and the Minister of Health intimated plainly that for considerations of general public policy they would be compelled to advise the House of Commons not to give the bill a second reading. The deputation was introduced by Mr. William Graham, senior member for the city, who was accompanied by Dr. Drummond Shiels. Despite the Ministerial declaration of hostility, a number of members interested in the subject held that the Edinburgh Corporation should not withdraw the bill forthwith, but claim a second reading debate on it in the House of Commons. It was pointed out that bills introduced by other corporations to secure additional powers for controlling venereal diseases had received a second reading and been sent to committees. Other members, however, suggested that to press on the Edinburgh bill to certain defeat would prejudice the chances of the bill which the Glasgow Corporation contemplates introducing on the same subject. On the following day (March 16th) the second reading of the Edinburgh Corporation Bill was formally moved in the House of Commons. Objection being taken, the bill was put down for that day week.

#### Tuberculosis in the Navy.

In a reply to Admiral Beamish, on March 14th, Colonel HEADLAM furnished the following totals of incidence of pulmonary tuberculosis in the Royal Navy in the years 1922 and 1925, the latest available: Commissioned officers, 8 cases in 1922, 6 cases in 1925; available: telegraphists, 12 and 12; engine-room ratings, seamen, 91 and 107; sick-berth staff, 4 and 5; 49 and 58; other artisans, 3 and 9; ship's cooks, 5 and 12; writers, 4 and 0; supply staff, 2 and 5; ships' cooks, 5 and 12; Royal Marines, 10 and 16.

On March 15th, when the Navy Estimates were introduced and discussed, Admiral BEAMISH referred to the incidence of tuberculosis in the navy, a topic which the House had discussed in the previous week. He said this incidence in naval personnel had for years been higher than in the army or in the rest of the population. He called for immediate investigation and action.

Colonel HEADLAM, replying to the debate for the Admiralty, said the previous debate on the subject had shown that all sides in the House felt something was wrong. He agreed that the men themselves might be more satisfied if they had recourse to some outside board, but he pointed out that the independent tribunals of the Ministry of Pensions were set up to meet the special circumstances arising out of the war, when the medical history of thousands of cases could not be ascertained in the ordinary way. In the navy in ordinary times the medical history of a man was known from the moment he first came on board. Every detail of his case was known. The doctors forming the survey board before which he came were familiar with the kind of service he had, and were therefore better fitted than almost anybody else to judge whether the illness from which he was suffering was due to service. The man who came before such a survey board had the doctors on his side as far as was possible, and was given every chance of stating his case and of calling witnesses. Mr. GROVES, intervening, said he disputed that. Colonel HEADLAM, proceeding, said medical boards of survey were held twice in each month under the authority of the Commander-in-Chief or senior officer present. The board consisted of the medical officer in charge of the hospital, who acted as president, and three medical officers, two being senior medical officers of the hospitals and one a senior medical officer of the fleet or depot. The Admiralty had considered the suggestion that there should be an executive officer on the survey board, and the opinion was that nothing would be gained by reverting to a practice which was abandoned in 1914. An executive officer would either interfere with the medical officers in the performance of their duties or would be a mere figurehead. The medical officer who brought the case forward appeared before the survey board so that the surveying officers should receive full information on the case. A complete history of each case was made out, showing the details of the onset, the course, and the final state of the disability. Before survey the officer or rating was required to fill in a form on which he was asked to state what, in his opinion, caused his disability. The board was required to investigate and record whether the disability was attributable to or caused by service (pre-war, war, or post-war), and if not, to what specific condition it was attributed. These reports, with a statement by the officer or man, were sent to the Commander-in-Chief, who made his decision whether the man should be invalided.

Dr. VERNON DAVIES asked if the board decided the case simply from the medical history sheets of the man. Colonel HEADLAM said the board saw the man. After the Commander-in-Chief had decided, the case was sent to the Admiralty, where every case was carefully investigated by the medical authorities, comparison being made with reports and records from ships or establishments where the man had served. The question of attributability was decided by the medical officers at the Admiralty. These had all the papers before them. Commander KENWORTHY: Everything except the patient. Colonel HEADLAM said that if there was any bias at the Admiralty it was on the side of the man. Appeals for reconsideration of awards could be made by the men themselves or by organizations on their behalf. The regulations on which attributability or aggravation was assessed were set out in a secret and confidential memorandum to the surveying officers. They were based on the report of the Post-War Disability Committee and were applicable to cases arising in the Navy, Army, and Air Force. Dr. DAVIES interposed the remark that the great difficulty was tuberculosis. Colonel HEADLAM replied that there were other diseases. It might be fair to say that the rules by which these cases were judged were too severe and that the doctors were not given sufficient latitude. That might easily be the case, but to blame the Admiralty authorities was unfair. Sir Bertram Falle had in the previous debate cited cases of the year 1920, in which the claims to attributability had been rejected by an independent appeal tribunal under the Ministry of Pensions. The truth was that the rules were of importance, and not the tribunal. The admission of a man to the navy as fit simply meant that an examination had found nothing sufficiently wrong to make it impossible for him to enter, but did not however, that the whole matter required careful attention, and they were looking into it from all aspects. A joint committee of hygienic conditions in the navy had been referred to a special medical consultative board of outside specialists, whose report would guide the Admiralty to some extent in its policy. The cases were properly and fairly judged. That applied to tuberculosis. It was easy to exaggerate about tuberculosis in the navy. The incidence of that disease seemed to be less in the navy than in civil life, but the conditions of inspection were such that the cases were found out early.

The House passed to other naval topics.

#### *Incidence of Disease in the Navy.*

On March 19th Colonel HEADLAM, in reply to Mr. Hore-Belisha, gave a list of the disabilities for which recruits to the Royal Navy and Royal Marines were discharged within twelve months of their engagement in 1926 and 1927 respectively. He said that of diseases caused by infection, 4 recruits were discharged in 1926 and 1 in 1927 for pneumococcal infection (lungs); 6 and 8 in the respective years for rheumatic fever; 11 and 7 for pulmonary tuberculosis; 3 and 5 for non-pulmonary tuberculosis, and 3 and 3 for other figures were: Diseases of the spinal cord, 1 and 1; paralysis, 1 in 1926, 11 and 15; insanity, 2 and 4. Diseases of the eye, 34 and 21; of the ear, 66 and 66; and of the nose, 2 in 1927. Diseases of the circulatory system: diseases of the heart—organic 29 and

32, functional 2 and 6; diseases of the arteries, 1 and 1; diseases of the blood and spleen, 1 in 1926. Diseases of the lymphatic system: 1 in 1927; glands and internal secretion, 4 and 2. Diseases of the respiratory system: bronchitis, 2 in 1927; asthma, 2 and 2; fibrosis of lung, 3 and 4; pleurisy, 3 and 2; other diseases, 1 in 1926. Diseases of the digestive system: teeth and gums, 2 and 3; mouth, palate, fauces, and pharynx, 1 in 1926; tonsillitis, 1 in 1926; stomach, 1 in 1927; intestines, 1 in 1926; hernia, 3 and 1; rectum and anus, 1 in 1927. Diseases of generative system: varicocele, 3 in 1927. Diseases of organs of locomotion: periosteum and bone, 1 in 1926; cartilage and joints, 2 and 1; spine, 1 in 1926; muscles, fasciae, tendons, hursae, 1 in 1927; deformities of limbs, 11 and 11. Diseases of arcolar tissue and skin: eczema, 1 and 1; other skin diseases, 2 in 1927. Diseases of urinary organs: kidneys, 5 and 5; ureter and bladder, 2 in 1927; urinary disorders, 22 and 12. New growths, non-malignant, 1 in 1926; local injuries, injuries and wounds, 9 and 5. Totals: 1926, 261; 1927, 250.

#### *Dangerous Petrol: Protective Clause in New Bill.*

The bill for the amendment of the Petroleum Acts was considered by the Standing Committee of the House of Commons on March 20th, when Lieut.-Colonel Sir VIVIAN HENDERSON, who was in charge of the bill, moved a new clause empowering the Home Secretary to make regulations as to classes of petroleum likely to be dangerous or injurious to health. He said the Government intended to introduce a Consolidation Act in regard to the law governing petroleum and petroleum spirit, but it was desirable that certain amendments should be passed first. With regard to the recent controversy concerning dangerous spirit, the Home Secretary had set up a committee of inquiry which was asked to act expeditiously and report. The new clause would enable the Home Secretary to take such action in the framing of suitable regulations as might be deemed necessary on receipt of the report. The clause was added without opposition.

*Petrol Fumes in Armoured Cars.*—On the report of supply in the Army Estimates, on March 20th, Mr. HARRIE asked what was being done to protect men in the armoured cars and tanks from petrol fumes. Sir LAMING WORTHINGTON-EVANS replied that the army did not use ethyl-petrol at all. They had an experimental depot at Woolwich, which was constantly experimenting with a view to discovering means of saving human life, and of improving defence at the same time.

*Smoke Abatement.*—Sir KINGSLEY WOOD, replying to Mr. Naylor, on March 20th, said that by-laws respecting the emission of smoke had been made by fourteen local authorities, and confirmed. Two regional advisory committees and one executive committee had been set up since the issue of the Ministry of Health's circular calling the attention of local authorities to the Smoke Abatement Act of 1926, in addition to two advisory committees previously appointed. A committee had also been appointed by a conference of representatives of local authorities to report on smoke abatement in the Greater London area.

*Health Conditions in Artificial Silk Factories.*—Sir WILLIAM JOYNSON-HICKS told Mr. Kelly, on March 15th, that reports on artificial silk factories by medical and other inspectors of factories who had visited them showed that the conditions of health were generally satisfactory, but cases of conjunctivitis had occurred at one or two works, and there had also been cases of dermatitis. Suitable precautions were being taken, and the conditions would continue to receive the special attention of his medical staff. He could not answer without notice regarding individual firms or factories.

*Dispensing of Medicines in the Navy.*—Dr. VERNON DAVIES asked, on March 14th, if the First Lord of the Admiralty was aware that the dispensing of medicines for men in the army by dispensers who underwent a short period of training was, in the opinion of the army authorities, performed adequately and economically; and whether he would, in the interests of economy, introduce the same system into the navy, and not engage any more fully trained pharmacists. Colonel HEADLAM, Financial Secretary to the Admiralty, said he could not accept the suggestion that the replacement of fully trained pharmacists in the naval service by dispensers trained in the manner proposed would make for economy, nor did he think the conditions in the two services so analogous as to make such a change practicable. Fully trained pharmacists were employed only in naval hospitals and in the naval medical store depot. Pharmacists carried out other duties besides those of dispensing. They were responsible, in addition, for the supply of medical stores to the fleet and for medical store duties in hospitals. Sick-berth ratings were instructed in dispensing duties only so far as they related to the stores in the service afloat scales, and performed such duties under the supervision of the medical officer of the ship, who was personally responsible for the correct issue and use of all drugs. Dr. DAVIES asked whether Colonel Headlam held that there was a difference between dispensing for the navy and dispensing for the army. Colonel HEADLAM said that he could not answer for the army.

*Fitness for Labour of Vagrants in Casual Wards.*—Replying, on March 15th, to Mr. Grundy, Mr. CHAMBERLAIN said medical advice would not be obtained on the diet to be supplied to vagrants in casual wards where stone-breaking had been introduced. The dietaries were reconsidered in 1925 in the knowledge that casuals might have to break stones. He would not order medical examination to make sure of the physical fitness of the vagrants who broke stones. No task was required from a casual suffering from temporary or permanent infirmity. Mr. LANSBURY asked if it was not a fact that there were no medical officers at casual wards, and that no casual was medically examined before being set to

after referring to the British Empire as being the brightest jewel in the Irish Crown, commented on the valuable work of Irishmen and by the association in promoting co-operation between different parts of the Empire. Mrs. Claude Bettington, who also replied to this toast, delighted the audience with a stream of anecdotes suited, as she remarked, to a meeting which might have been presumed to consist largely of medical students. The toast of "The President and the Association" was proposed by Dr. Bertram Watson, and in his reply Mr. G. W. Dawson referred to the progress made during the fifty years of its existence. Songs were rendered by Miss Mary Sheridan, Mr. Patrick Hughes, and Wing Commander Tyrrell, and these contributed much to the pleasure of an audience numbering more than one hundred.

A PARTY of forty-five medical students from Scotland arrived in London on March 17th to devote five days to a programme of demonstrations, including operations, at various London medical centres, among them being the Royal College of Surgeons, the leading hospitals, the Radium Institute, and the Wellcome Historical Medical Museum. The arrangements were made by the National Union of Students.

THE London School of Hygiene and Tropical Medicine has ordered from Messrs. R. and J. Beck, Ltd., more than two hundred microscopes for use in the new laboratories now in course of construction in Gower Street. The microscope is of British manufacture and embodies certain special features. The base is of rigid construction and the foot combines the advantages of the horseshoe or Continental model with the so-called English foot. The stage is of the completely built-in mechanical type with travel of  $1\frac{1}{2}$  in. + 1 in., the entire top plate of the stage forming the moving part. On the stage a slide-holder of new design is provided, in which the slide is firmly held without springs. The fine adjustment is of the double lever pattern, operated by milled heads on either side. The body is 2 in. in diameter and is provided with an adjustable graduated drawtube. The substage is actuated by rack and pinion, and all substage appliances are carried on Akeley slides; thus the interchange of illuminating systems is both easy and accurate. The optical equipment is ample for all bacteriological requirements, and the objectives are to be coloured externally so as to enable them to be recognized at sight. Messrs. Beck have agreed that certain rigid tests shall be applied to the whole equipment before delivery is accepted.

THE report of the Joint Tuberculosis Council for 1926 and 1927 contains a brief account of the activities of that body since the issue of the last report more than two years ago. Reference is made to the report of the committee on the employment of tuberculous persons issued in 1926; the work is being continued, and a further report is promised in due course. The promotion of post-graduate courses for tuberculosis workers remains one of the council's main activities, and the research committee has presented a report on disinfection in tuberculosis which it is intended to embody later in a memorandum. A special investigation is being carried on in Lancashire on the fate of young children in tuberculous households. The council has decided that evidence be offered to the Royal Commission on Local Government. A committee appointed by the council to consider this question concluded that for tuberculosis administration large areas were best; these alone could provide adequate salaries for experts, together with facilities for diagnosis, treatment of patients, and training of tuberculosis workers. The Council is represented by Dr. C. G. Hawthorne and Dr. Arnold Lyndon.

THE third annual report of the North Kensington Women's Welfare Centre has now been issued, and may be obtained from the secretary, 12, Telford Road, Ladbrooke Grove, W.10. A supplement for medical readers is provided on request; it gives details of the contraceptive methods recommended at this centre.

THE Astor challenge shield, given by the National Baby Week Council for the most effective local baby week campaign in 1927, has been awarded for the third year in succession to the Northampton Maternity and Infant Welfare Voluntary Association, and therefore passes into the permanent keeping of that body. A special trophy has been given to Leicester Health and Baby Week Committee, which took second place, and certificates of merit to Kettering U.D.C. Ladies Voluntary Committee for Infant Welfare, Kingston-on-Thames Infant Welfare Centre, and Sunderland County Borough. A campaign organized by the Cambridgeshire Federation of Women's Institutes gained the William Hardy challenge shield, reserved for smaller areas.

THE fourteenth annual general meeting of St. Andrew's Hospital, Dollis Hill, for the professional and middle classes, was held under the chairmanship of Cardinal Bourne. It was reported that there had been a considerable increase in the

number of in-patients throughout 1927, and emergency accommodation had to be provided. The year ended with a deficit of £1,076 and a building debt of £281. Funds are required for new buildings, including a children's ward and a nurses' home, which will release additional accommodation for patients. In all £30,000 is needed for these and other developments. In response to an appeal made a year ago for £15,000 to enable building to be started according to plans approved by King Edward's Fund, £6,107 has been given or promised. The hospital was opened in 1913, and although contributions are asked from patients who can afford to pay, no patient, it is stated, has ever been refused, whatever his nationality or creed, solely on the ground that he could not pay a fee.

THE Cambridge University Press announce for early publication a volume of essays and addresses by the late William Bateson, F.R.S., edited, with a memoir, by Mrs. Bateson; and *Common Principles in Psychology and Physiology*, by Dr. J. T. MacCurdy.

AN international post-graduate course on modern therapy, with practical clinical work, will be held in Vienna from June 18th to 30th. Further information may be obtained from the secretary of these courses, Dr. A. Kronfeld, Porzellangasse 22, Vienna IX.

AT a recent meeting at Scheveningen, which was attended by delegates from twenty-five countries, it was decided that the international congresses of ophthalmology which had been interrupted by the war should be resumed. Professor van der Hoeve was elected president and Professor Lunds-gaard vice-president. An executive committee was appointed, consisting of Drs. Axenfeld (Germany), Mellor (Austria), Coppez (Belgium), Byers (Canada), Marquez (Spain), Morax (France), and Orto (Italy).

THE International Labour Office has published the December issue of its *Bibliography of Industrial Hygiene*, which contains recent papers on hygiene in general, industrial medicine, physiology, and pathology throughout the world. Copies may be obtained from the International Labour Office, 12, Victoria Street, S.W.1.

PROFESSOR R. KRAUS of Vienna has recently been invited by the Republic of La Plata to become the director of an experimental therapeutic institute.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9361, 9362, 9363, and 9364** (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Aitology Westcent, London.*

FINANCIAL SECRETARY and BUSINESS MANAGER, *Westcent, London.*

M

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*); telephone: 4737 (Dublin), and of the Scottish Office, 6, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

## QUERIES AND ANSWERS.

"Q." asks for suggestions for the treatment of a case of "masturbation" in a male child, aged about 20 months, circumcised in infancy, and with no local irritation present.

## FINISH FOR MOTOR CAR BODIES.

AN expert, to whom we have referred a query from a correspondent

states that cellulose finish is with-  
out paint and varnish for motor car  
fast colour, and ease of cleaning,

but it is not, as a rule, suitable  
have raised mouldings, served  
steel bodies or aluminium panels,  
which  
With  
cellulose  
finish is usually more durable.

## TREATMENT OF LYMPHATIC OBSTRUCTION.

DR. A. N. LEEMING (Old Colwyn) asks for advice as regards the treatment of a woman, aged 70, with considerable lymphatic swelling (resembling elephantiasis) in the suprapubic region, and also, to a less extent, of the left thigh and leg. The condition has been progressive, in spite of treatment, for the last six months. Her organs are sound, except that there is proctodentia, for which a pessary was worn for many years, but has now been abandoned. The treatment has been lotions; ointments, including zinc; mercurials; iodex; radiant heat; x rays every ten days; general, as for gout; colossal manganese; and rest in bed.

## CRAMP AFTER SCIATICA.

"F. W. S." writes in reply to "K." (March 10th, p. 430): This is due to irritation in the motor fibres of the great sciatic nerve. People who suffer from it generally have a subnormal temperature, and the effective remedy is heat. A warm bath on retiring, the temperature of which is gradually raised until it is as hot as the patient can bear, with plenty of covering on the bed afterwards, will generally ensure a comfortable night's rest. Radiant heat and diathermy are helpful, and vapour baths are perhaps best of all, as they encourage elimination. Finally, the patient's evening temperature can be raised by giving iodo-tirosinamin. By taking  $\text{mxxv}$  to  $\text{mxxx}$  after breakfast I was able to raise my own temperature to  $99^{\circ}\text{F}$ , or a little more, every evening for two months, and this did not cause any inconvenience or discomfort. It cured both sciatica and cramp.

## PRESERVING THE STERILITY OF HYPODERMIC SYRINGES.

DR. R. J. GITTINS, Medical Superintendent, Friends' Mission Hospital, Itarsi, Central Provinces, India, writes in answer to the inquiry of "Intramammary" (*Journal*, November 12th, 1927, p. 905):—The method which we have adopted and found satisfactory in this hospital for the past two years or so is as follows: After initial sterilization by boiling, the hypodermic syringes are placed in rectified or methylated spirit in a jar (previously sterilized), to which is fitted a screw cap. Such jars are obtainable for a few pence. The needles are placed in a suitable receptacle in petrol, which we find is a far better preservative than spirit, lysol, or chloroform, which we have also tried. A pair of forceps are kept in lysol for lifting out the syringes and fitting on the needles. Our injection solutions are placed in bottles, closed by small pieces of rubber, such as old cycle tubing, which is securely tied round the necks. In one bottle is kept sterile saline or distilled water, which, before giving an injection, is drawn into the syringe in order to remove traces of spirit and petrol. After the injection the syringe is replaced in the spirit jar without disassembling and the needles in the petrol, where they remain till next required. We have found this method quite reliable, and on the few occasions when there has been slight sepsis following injection we have traced it to a contaminated injection solution. We have employed syringes and needles straight out of these preservative solutions for intravenous injection without disaster. After use for intravenous injection it is our rule to re-sterilize the syringe by boiling, in order to avoid all risk of transmission of syphilis or other infection. We rely on spirit for cleaning the rubber caps of the injection bottles. We usually add small quantities of some antiseptic, such as one-half per cent. phenol or salicylic acid, to our injection solutions or the distilled water, with the object of dealing with any infection which might be carried into the bottles on the insertion of the needles through the rubber caps. These methods have proved quite satisfactory, and we must have given some thousands of injections since we established the system.

## INCOME TAX.

## Allowance after Marriage.

"J. K.," who was married on March 14th, asks what personal allowance he can claim for the year ending April 5th. \* \* \* Under Schedule 18 of the Finance Act, 1920, the married allowance of £225—in lieu of the single allowance of £135—is due if the claimant "has his wife living with him for the year of assessment." The Act does not stipulate that it shall be for the whole of the year of assessment, and we understand that in such circumstances as those of "J. K." the full allowance would be granted for 1927-28. He should therefore communicate with the local Inspector of taxes asking for the statutory form of declaration for relief as a married man, and suggesting that the full relief should be credited to the payment due from him on July 1st next.

## Replacement of Car.

"SATIS" bought a two-seater car in 1901 for £500, and has now replaced it by a four-seater car costing £295, less £35 allowance for the old car—that is, £260 net. Depreciation has not been claimed.

\* \* \* He should claim the amount actually expended—that is, £260. In view of the cost of the former car and the fact that no allowance can be claimed on this transaction for the balance of the loss incurred, it is thought that the authorities would not press the fact that the new car provides more accommodation. It is, however, arguable from the Revenue side that the £260 should be reduced by the difference, as regards the new make of car, between the two-seater and four-seater models.

## LETTERS, NOTES, ETC.

## PRECOCIOUS MENSTRUATION?

WE have received the two following clinical accounts of cases both of which the diagnosis of precocious menstruation has been suggested:

DR. J. A. KENDALL (Brixton, S.W.) reports the case of a child born in May, 1920, from whom on four occasions, at regular monthly intervals, there has been a slight blood-stained vaginal discharge, lasting for an hour or two. The first appeared about October 18th, 1927, successive ones occurring about the same time in November, December, and January. The discharge was slight and rarely amounted to more than a stain on the clothes. The child is healthy, precocious, and well developed for her age; she suffers from night terrors. At the times when the discharge appeared she became fretful, complained of headache, and had dark rings under her eyes.

DR. J. A. NOBLE (Husbande Bosworth, Rugby) states that a primipara, aged 23, gave birth to a female child, weighing 7 lb., on December 4th. Four days later blood commenced to pass from the vagina and continued until December 12th. The vulva was congested and the vagina was filled with a chocolate-coloured discharge; the breasts were purple and swollen, and a hard area surrounded the nipples. A drop of fluid resembling colostrum was easily expressed. With the cessation of the flow the breasts became normal. The discharge was examined microscopically on the sixth day, when the red cells were found to be diminished and the swab showed chiefly polymorphonuclear cells, with mucus and epithelial debris. Dr. Noble was assured that there had been no interference with the nipples. During the subsequent seven weeks there was no further sign of ovarian activity or disease.

## GAS GANGRENE FOLLOWING A ROAD ACCIDENT.

DR. W. B. BURKE (honorary surgeon, Victoria Hospital, Workson) writes: The report of two similar cases of gas gangrene in the *British Medical Journal* of December 24th, 1927 (pp. 1183 and 1184), suggest that the following notes may be of interest:

A married woman, aged 30 and apparently in perfect health, was admitted to the Victoria Hospital on May 30th, 1927, and placed under my care. In a motor cycle accident the pillion foot rest was driven into the right foot, causing a wound 3 or 4 inches long on the inner border of the sole of the foot; three sutures to stop haemorrhage had been inserted before admission. On examination under anaesthesia the head of the first metacarpal was found to be fractured. The wound was thoroughly cleaned; it was not particularly dirty. Bipp was rubbed in and sutures were inserted. On the next day much thin, evil-smelling discharge came from the wound, and bullae, containing dark fluid, were present near it. The leg was swollen and oedematous to within a few inches below the knee, and presented patches of brownish-red discoloration to the same level. The smell suggested gas gangrene, and amputation above the knee was contemplated. There were no constitutional symptoms. Under an anaesthetic it was found that all muscles of the calf, except the soleus, had undergone softening, having degenerated into brown pulpy masses containing gas. Amputation through the middle third of the thigh was performed; the muscles and other tissues at the level of the amputation seemed perfectly healthy. On June 2nd the stump seemed healthy in all respects, but towards evening constitutional symptoms developed and the temperature rose. The brownish-red discoloration reappeared in the stump on the next day, toxæmia was well established and became progressively more severe. The gangrene spread up towards the iliac region, and the patient died on June 6th.

Judging by the two cases in the *Journal*, and from investigation of the literature on the subject, I can only conclude that this case would have yielded to serum therapy, but as such cases are few and far between in general practice, it is a matter of life and death.

## A COINCIDENCE.

CAPTAIN H. WILLIAMSON, I.M.S. (Quetta, India), writes: In view of its possible medico-legal interest the following case seems worthy of publication. A short while ago a child, aged 18 months, was brought to me with a naevus at the inner canthus of the left eye. I told the mother to bring the child to hospital on the following Wednesday, when I would remove the naevus. She did not bring the child on the Wednesday, so the naevus was not touched, but on the following Saturday the child was admitted suffering from a sudden and fulminating attack of meningitis, from which it died twelve hours later. The diagnosis was confirmed post mortem. Had I removed the naevus I could not have avoided the conclusion that meningitis, occurring three days later, was the result of infection from the operation.

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 42, 43, 45, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 100.

## Remarks

ON

## ADVANCES IN THE TREATMENT OF CANCER OF THE CERVIX UTERI.\*

BY

HERBERT R. SPENCER, M.D.,

CONSULTING OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

It was with some diffidence that I accepted the invitation to open a discussion on advances in the treatment of cancer of the cervix, for the reason that, since I retired from practice, just a year ago, my personal advance has been in the temporal rather than the gynaecological direction. But 'tis a pleasant thing, says Lucretius,† to watch our colleagues toiling, especially when they are at sea, and as lookers-on proverbially see most of the game, having played the game for forty years, perhaps I may be able to point out some advances which have been made, some advances which need making, and some methods of inquiry which give a false impression of the fact, the degree, and the direction of advance.

In this last connexion I would emphasize the futility of placing any reliance upon statistical inquiries based upon insufficient data, with which the literature of the subject abounds. These statistics purport to give the "absolute cure" rate of various methods of treatment in figures carried to two places of decimals, and if, like a celebrated Chancellor of the Exchequer, you inquire the meaning of those "damned dots," you will usually find that neither they nor the integers have any value, and that the "absolute cure" rate thus expressed is absolute cant. To ascertain the "absolute cure" rate—that is, the proportion of patients cured (after, say, five years) to patients seen—is a difficult matter on account of the large numbers concerned, the want of compulsory notification of cancer, and the absence of particulars of the treatment in the death certificates of patients who have been affected with cancer; but it may be done for small numbers without much difficulty, and I appeal to the younger gynaecologists to follow up, for a period of five or ten years the first ten or twenty cases seen, and give full particulars, with the microscopic appearances of the cases and the final results; thus figures will be available for replacing the misleading statistics of the present day. I have done this for my cases of cancer of the cervix complicating pregnancy, of which the whole of my experience has been given.

In dealing with statistics it is very important that no case should be accepted as cancer unless it has been examined microscopically by experts in gynaecological pathology. The Obstetrical Society of London, more than a quarter of a century ago, established a pathology committee to which cases could be referred, and this continues to function in the Section of Obstetrics and Gynaecology of the Royal Society of Medicine, and is, so far as I know, peculiar to this country. The result has been that many English gynaecologists have devoted themselves to the study of the pathology of cancer of the cervix, and specimens accepted by that Section may be relied upon as true examples of cancer, whereas the mere statement that a case is cancer, without examination, carries with it no such conviction.

I lay the more stress upon the importance of this advance in gynaecology because certain conditions closely resemble cancer of the cervix, and can only be diagnosed by those who have an expert knowledge of gynaecology. I may mention a few of these: erosions, leucoplakia, papilloma, adenoma, mucous tubercle, chancere, corroding ulcer, syphilitic and tuberculous ulcer, chorion epithelioma; and one—carcinoma adenomatodes (adenoma malignum)—in which even microscopic examination may lead to error. Having seen examples of all these conditions, in view

of the paucity of cases which have been published, I cannot help feeling that among the long lists of cases of "cancer" operated on some may have owed their non-recurrence to their non-malignant nature.

Another direction in which advance is needed is in the early recognition of the cases, in advocacy of which I read a paper<sup>2</sup> at the meeting of the British Medical Association in 1907. I am hopeful that some benefit has resulted from that paper, and the discussion to which it gave rise, at all events in getting the doctors to examine their cases, though I am doubtful whether further measures are not needed for bringing the importance of early treatment before the public. I have found the visits of patients to the clinic on the anniversaries of their operation to be a valuable means of bringing the subject before hospital patients.

## PREVENTIVE TREATMENT OF CANCER.

In the absence of knowledge of the essential nature of the disease the preventive treatment of cancer of the cervix is difficult. It is known that cancer of the cervix is almost limited to patients who have practised sexual intercourse, and mostly occurs in those who have had one or many pregnancies. Analogy with experimental cancer leads us to suspect the irritation of lacerated and inflamed tissues as likely to lead to cancer, and they have been known to be followed by the disease. Treatment of these sources of irritation is indicated, and, in rebellious cases, removal of the cervix is called for.

One great advance in the prevention of cancer has been obtained by the substitution—for example, in cases of myoma—of total hysterectomy for the subtotal operation, thus avoiding cancer of the cervical stump, which has caused the death of several hundreds of women. It is a discredit to gynaecologists that these deaths should occur. I am glad to say that I abandoned the subtotal operation twenty-eight years ago; it would gratify me more than the last line of the quotation from Lucretius if my colleagues would do the same.

## ADVANCES MADE.

I will now consider the advances which have been made in the treatment of cancer of the cervix.

Omitting a few pessimists, to whom I have alluded in the paper mentioned, it will be generally admitted that remarkable progress has been made during the hundred years that have passed since Blundell removed a cancerous uterus in 1828;—this was the first time that the cancerous uterus was successfully removed in this country.†

James Blundell, obstetric physician to Guy's Hospital, in 1825 wrote a valuable paper on "Researches physiological and pathological," which was not considered worthy of publication by the Medical and Chirurgical Society. The author published the paper privately in 1825; the copy of that paper in the library of the Royal College of Surgeons contains some manuscript notes by Blundell concerning the case of cancer of the cervix, and the specimen—preserved in the museum of the Royal College of Physicians—I am able, through the courtesy of the curators, to show you.

The experiments on animals, performed by Blundell had an important influence in the development of abdominal section, and his case of vaginal hysterectomy for cancer of the cervix enlarged the field of operative treatment, which, until recent times, was the sole means of cure at our disposal. Hopeless indeed had been the outlook for patients from the earliest times of which we have records.

The Anglo-Saxon leech (about A.D. 900) treated cancer by applying the ashes of a hound's head to the wound: "if it will not yield to that take a man's dung, dry it, thoroughly rub to dust, apply it. If with this thou art not able to cure him thou mayest never do it by any means." Even as late as 1791 Lowder wrote of cancer of the uterus, "This is a disease so incurable that physicians give it up."<sup>4</sup>

That gynaecologists of the twentieth century are more hopeful is shown by the many researches in which they are engaged, of which I need only mention that of Thies on immunization by cancer-albumin and implantation of

\* Made in opening a discussion at the Medical Society of London on March 26th.

† *Suave, maris magno furantibus aequora ventis,  
E terra magnum alterius spectare laborem;  
Non quia vexari quemquam est jucunda voluptas,  
Sed, quibus ipse malis careas, omnia cernere suave est."*

<sup>2</sup> The patient survived the operation nearly a year, dying on February 7th, 1829. Blundell also removed the cancerous uterus from three other patients, with fatal results.

<sup>4</sup> Sauter of Constance, in 1822, was the first to perform the operation successfully.

cancer; and of Blair-Bell on the treatment of the disease by lead, which he brought before this Society in 1926: it is too soon to pronounce an opinion on the value of this treatment, but its dangers have been pointed out by its originator. For the present, at any rate, the treatment of cancer of the cervix resolves itself into removal of the growth by operation or by radiation.

#### OPERATIVE TREATMENT.

Passing over the destruction of the growth by caustics or cautery and the simple removal of the cervix (first carried out by Oslander<sup>5</sup> in 1801), the operative treatment may be divided into high amputation of the cervix and vaginal and abdominal hysterectomy.

##### 1. High Amputation of the Cervix.

High amputation of the cervix, preferably by the electric cautery introduced by Byrne, is an excellent treatment for early cases, especially in elderly patients; it is free from risk and permits the continuance<sup>6</sup> and the subsequent occurrence of pregnancy,<sup>7</sup> in which respects it is superior to any form of hysterectomy. In patients operated on before the menopause it is sometimes followed by stenosis and dysmenorrhoea until the menopause occurs; yet even these patients have better general health than those who have been deprived of uterus and ovaries. I have watched such a patient for twenty-five years after the amputation, during which she has been able to fulfil her conjugal duties without trouble; in this respect also high amputation is superior to any kind of extended hysterectomy. It is the fashion to neglect this operation; but, in the case of an early cancer in an elderly subject, it is, in my opinion, the best means of operative treatment at our disposal.

##### 2. Vaginal Hysterectomy.

(a) Simple vaginal hysterectomy was first successfully performed in this country by James Blundell on February 12th, 1828. Various are the methods of carrying it out. The use of the cautery, which I have constantly employed, has, I think, some advantages in lessening the hæmorrhage at the operation and the frequency of recurrence of the growth. The whole operation is carried out with the cautery; but it is generally necessary to tie the uterine arteries and the broad ligaments. The vaginal operation has a very low rate of immediate mortality, and it has the advantages over the extended operation that it does not interfere with marital intercourse, nor, like the abdominal operation, give rise to scar-hernias. The minimal risk of the operation renders it of great value in enfeebled or aged patients. The superiority of the recovery over that after abdominal hysterectomy is so marked that it is surprising that there exist gynaecologists who never perform the operation.

(b) Extended vaginal hysterectomy consists in a more extensive removal of the tissues with the help of para-vaginal incisions, unilateral or bilateral, which facilitate the isolation of the ureters and very free removal of the cellular tissue. The operation, carried out with varying technique by Schauta, Thaler, Peham, Stöckel, and others, has a higher mortality rate than the simple operation, but it has been reduced to 2.7 per cent. by Peham, who claims an "absolute cure" rate of 31.13 per cent., against 27.9 per cent. for the extended abdominal operation.<sup>8</sup> This is a very remarkable result, and is probably due to the lower mortality of the vaginal operation; for all vaginal operations have the disadvantage that the removal of many glands is impossible. The removal of all the pelvic glands is, of course, impossible by any operation, and it may be that the extensive removal of glands and cellular tissue has other disadvantages than that of increasing the risk of the operation.

The remarkable results obtained by the extended vaginal operation have somewhat withdrawn the attention of gynaecologists from the abdominal operation, in which the chief advantage lies in permitting the removal of infected glands. The extended vaginal hysterectomy, like the extended abdominal operation, interferes with marital intercourse.

In all kinds of vaginal hysterectomy it is important that the peritoneum should be carefully closed; gauze introduced into the peritoneum for drainage sometimes gives rise later on to intestinal obstruction produced by intestinal adhesions set up by the gauze.

##### 3. Abdominal Hysterectomy.

(a) Simple abdominal hysterectomy is useful in cases where there are complications (uterine fibroids, tumour of the appendages) and where the weakness or advance of the patient renders the extended operation inadvisable. It permits more careful closing of the peritoneum than the vaginal operation, is less likely to be followed by obstruction, and has a lower rate of mortality than the extended operation.

(b) Extended abdominal hysterectomy, which will always be associated with the name of Wertheim of Vienna, was proposed by him as a more surgical operation than the vaginal procedure, in that it permits the wide removal of the tissues and of the pelvic glands. The chief drawbacks to the operation are its high mortality, its late sequelae (fistulae and urinary infection), and the interference with marital intercourse which it entails. Although the mortality rate has been lowered by the employment of gauze drainage,<sup>9</sup> I have not seen any statistics showing the frequency with which drainage is followed by hernia of the scar and intestinal obstruction. The employment of drainage does away with the complete closure of the peritoneum, which is one of the advantages of operating by the abdomen, and favours the occurrence of hernia of the scar, the prevention of which is one of the advantages of operating by the vagina.

With regard to the removal of glands it is to be borne in mind that in about two-thirds of the patients operated on the glands are not cancerous, that the removal of glands (necessarily incomplete) increases the danger of the operation, and that it appears probable that cancerous glands can free themselves from cancer, especially with the aid of radiation. Many patients, however, have remained free from recurrence for as long as ten years after the removal of cancerous glands, which is a triumphant result of the extended abdominal operation.

##### 4. Combined Abdominal and Vaginal Hysterectomy.

Combined methods of operating (abdomino-vaginal or vagino-abdominal) have some advantages in lessening the exposure of the peritoneum and the danger of infection.

##### 5. Radiation Treatment.

Great indeed has been the advance in the treatment of cancer of the cervix since the employment of radium, mesothorium, and Röntgen rays. As my experience of this treatment only dates back about a dozen years, and my colleague is dealing with the subject, I will merely state that in my opinion it is the most important advance of all. Its curative effects are incontestable, and it is especially valuable in the treatment of cancer complicating pregnancy.<sup>9</sup>

#### CONCLUSION.

In conclusion, I wish to state my opinion that the treatment of cancer of the cervix should be eclectic and that no one treatment is suitable for all cases. During the past century a great advance has been made, so that to-day about two-fifths of the "operable" cases can be cured. This proportion might be doubled if the cases came for treatment at an early stage of the disease. The great desideratum is to get the cases early; they may then be treated by one of the methods mentioned. Of these the most hopeful for the future is the treatment by radiation, the technique and dosage of which merit the intensive study of British gynaecologists, which I am sure will be advanced by the contribution of our Belgian colleague, Max Cheval.

## TREATMENT OF CANCER OF THE CERVIX UTERI BY IRRADIATION.\*

BY

MAX CHEVAL, M.D.,  
BRUSSELS.

### Action of Irradiation on the General Condition.

In their recent works Professor Slosse and Dr. Reding of Brussels have demonstrated the action of the  $\alpha$  and gamma rays on the organism.

For that purpose the patient drinks a solution of dextrose (50 grams of puro anhydrous dextrose in 200 c.cm. of distilled water). The authors detect the quantity of sugar in the blood by Hagedorn and Jensen's method. They found that the glycohaemia is more intense and has a longer duration in patients with malignant tumours than in the others.

These authors have shown also that cancer patients have a pH above the normal. When these patients are cured by a surgical operation this state may persist for years. On the other hand, if they are treated and "cured" by irradiation these symptoms disappear.

Having no personal experience of the utilization of  $\alpha$  rays I shall not speak of them, but will only indicate the improvements which seem to result from our practice in the treatment of patients by radium. To explain these improvements it seems useful to indicate precisely the technique which we have utilized since 1919.

### Technique of Curie Therapy.

In 1919 we utilized the utero-vaginal method of Professor Regaud, which consists in placing a certain number of tubes, suitably filtered, in all the length of the uterine cavity, and more tubes, also suitably filtered, in the vaginal culs-de-sac. Very early (1920) we gave up using needles with a weak filtration ( $1/2$  mm. of platinum), as their action was too caustic, and consequently too local (1 cm. in distance). We have given the preference to tubes filtered by  $1\frac{1}{2}$  mm. of platinum, plus aluminium  $1/10$  mm., plus rubber, plus gauze or cork. The distant action is greater and extends to a zone of 3 cm. around each tube.

Unfortunately the cervical canal is not always reparable, and we have had cases in which recurrence has taken place, the intrauterine cavity being the point of origin.

In the cases in which tubes could not be placed within the uterus we have, a month or two afterwards, made a vaginal application of radium. We have since 1922 performed subtotal hysterectomies by the abdominal route—the cervix is generally difficult to remove—followed by implantation of needles in the cervical stump, our motive being to destroy the malignant cells, which are too distant from the vaginal tubes; here the local action only is aimed at.

Having found that some of our patients presented recurrences in the neighbourhood of the parametrium, in 1922 we adopted the radium drainage method of Professor Daels. By this method tubes of radium may be placed outside the peritoneum in the neighbourhood of the external portion of the broad ligament. We have practised this without any operative accident, and have had a certain number of successes. We employed these methods combined up to 1926. Since then, Professor Regaud having drawn attention to the good results which followed the use of radium placed at a long distance, we have had constructed an apparatus containing 4 grams of radium element or  $7\frac{1}{2}$  grams of the bromide. We only use the very hard gamma rays. Our apparatus allows us to irradiate two patients at a time in large fields, as is done by the  $\alpha$  rays. The whole of the small pelvis is irradiated with an equal intensity, and, in spite of the enormous doses, the patient is neither rendered anaemic nor shocked. It is premature to speak of the results which this method will give, and to say whether it is useful to combine it with the local applications or with surgery; we have not used it sufficiently long to be able to discuss our results. Therefore we have only given a personal statistic ending in 1924; but we shall appeal to a large

\* Abstract of a contribution to a discussion at the Medical Society of London on March 25th.

number of authors of different countries to demonstrate that radium effects a cure in more than one-half of the operable cases; that in the cases on the limit of operability at least one-third are cured; and in inoperable cases 10 to 20 per cent. of the cases are cured.

### Conclusions.

1. Irradiation seems to effect cures of a better quality than surgery.
2. Of all cases treated by radiation 30 per cent. are definitely cured.
3. An improvement of this percentage should be obtained by the new methods, using large amounts of radium placed at a distance.

## An Address

ON

## THE CLINICAL STUDY OF PAIN:

WITH SPECIAL REFERENCE TO THE PAINS OF VISCERAL DISEASE.\*

BY

JOHN A. RYLE, M.D., F.R.C.P.,  
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL.

"Every pain has its distinct and pregnant significance; if we will but carefully search for it."—John Hilton.

OF all the symptoms for which we are consulted pain, in one form or another, is the most frequent and frequently the most urgent. Properly assessed it stands pre-eminent among the sensory phenomena of disease as a guide to diagnosis. And yet it must be confessed that our understanding of its nature and mechanisms, and consequently of its full significance in practice, remains peculiarly limited. We are naturally dissatisfied with invisible and imponderable evidence, and it is therefore no matter for surprise that recent years have witnessed the introduction into medicine of a host of objective methods of studying disease, and that the study of subjective symptoms has suffered some contemporary neglect. The opaque meal and enema; pycnography; cholecystography; the electro-cardiograph; methods of blood analysis; the various chemical tests for gastric, hepatic, pancreatic, and renal efficiency; bronchoscopy; lumbar puncture and its developments; and the exploratory operation—all these, following in the trail of the stethoscope and the ophthalmoscope and older routine methods of physical examination, bear witness to our zest for objective information. It is, however, chastening to remind ourselves that, notwithstanding all the help derived from a judicious employment of them, these methods too have their limitations, and none of them is infallible. They are chiefly useful in proving or disproving the existence of established organic disease; in increasing the accuracy of a clinical opinion; and in serving to differentiate one form of organic disease from another. They have greatly helped in decisions for or against operative intervention. They have undoubtedly exerted an instructive and a corrective influence. In some degree—although, to my mind, by no means so much as they might have done—they have even enhanced our appreciation of subjective symptoms. But their contributions to the early diagnosis of organic disease and to the study of functional disorders are necessarily restricted, and it is clear that without the initial indication of certain symptoms they could never be rationally employed. Moreover, their aid can rarely be invoked in urgent problems or in the homes of the people. There is a very real danger that by over-reliance on them, by too great an anxiety to give our patients the benefit of modern investigations, and by a waning confidence in our own clinical ability, we may come to lose the astuteness and wisdom of our forebears.

In medical education the introduction of these methods has not been an unqualified blessing, and the training of ear and eye and hand and the development of the power of inductive reasoning have suffered much. Every year I see a number of mistakes made through inappropriate,

\* Delivered before the Newcastle-upon-Tyne and Northern Counties Medical Society on February 2nd, 1923.

unnecessary, or excessive investigation. Not infrequently I have myself fallen into error for similar reasons; and not infrequently I have extricated myself from error by a return to first principles, by taking the history of the case again, or by making a more careful analysis of the patient's sensations—Nature's earliest signals of morbidity. It will be readily agreed that many of the best diagnoses and judgements are achieved with the unaided senses backed by experience. It will also be agreed that no course of action can train these senses unless it includes experience patiently garnered at the bedside and in the consulting room.

If I were asked how the next considerable advance is to be sought and won in the field of medicine I should say (with grateful acknowledgements to the influence of Sir James Mackenzie) by the intimate study of the physiology of symptoms, and (once more acknowledging our debt to other great pioneers in this field—notably John Hilton and Sir Henry Head) I would submit that our first concern should be a more extended and intimate study of pain.

This brings me to a consideration of method. New research into subjective phenomena does not commend itself to the laboratory worker, and cannot easily be pursued in the experimental animal. It is presumably for this reason that even the more recent textbooks of physiology are extraordinarily reticent on the subject of all excepting the superficial pains, and that the scanty references which they make to visceral pain are often misleading. (Thus they nearly all declare that visceral pain is very inaccurately located, and devote more discussion to the occasional sympathetic or somatic than to the far more frequent visceral sensations.) Experiments on the healthy human subject, such as those conducted by Hurst and his collaborators in the course of their work on the sensibility of the alimentary canal, are of necessity limited, and no amount of ingenuity can quite reproduce the experiments in disturbed sensation with which Nature herself provides us in our own bodies or those of our patients. The study of pain must therefore continue to devolve mainly upon the clinicians.

I wish that time would permit me to refer to the method and the classical contributions of the pioneers whose names I have mentioned, and to the valuable communications of others, including Ross, Hurst, and Copo in this country, and of Lennander, Rudolf Schmidt, and others abroad. For my present purpose let it suffice to recall that, whatever the individual trend of these investigators may have been—whether anatomical, physiological, surgical, or neurological—the basis of all their researches was clinical observation.

Partly because the immensity of the subject compels selective treatment, partly because visceral pains have especially interested me in my work as a general physician, and partly because they seem to me to have suffered neglect in comparison, for instance, with the pains of nervous disease, I have chosen to confine my attention in this paper to the subject of pain expressing visceral disease. My remarks will fall into three sections. In the first I shall endeavour to summarize the present state of our knowledge of the physiology of pains affecting the hollow organs. In the second I shall outline a simple system for the clinical analysis of such pains—a system which really embodies nothing new, and which is in large measure applicable to the study of other pains. In the third I shall consider, with examples, the practical applications of pain analyses, for, after all, the chief interest to the practising part of our profession of all such studies is their bearing upon the advancement of diagnosis, prognosis, and treatment.

#### VISCERAL PAIN.

The insensitiveness to ordinary tactile, thermal, and chemical stimuli of the serous and mucous coats of the hollow viscera has been established in various ways. Partly on this account Sir James Mackenzie became protagonist for the view that there is no true visceral pain, but only pain projected to the somatic tissues supplied by the same segment of the cord as that which supplies the injured viscus. This view still finds a few supporters, but common experience and experiment have rendered it untenable for the majority of students. There is reason to believe that

Mackenzie latterly modified his earlier view to that more generally upheld, for in 1922, in response to certain observations of my own, he wrote to me as follows: "It is to answer this question that I have spent a long inquiry and have come to the conclusion that the only known stimulus that produces pain in the tissues which are supplied only by the autonomic nerves is the contraction of muscle." I would prefer, for reasons which will become apparent, that we should state the matter a little differently by saying that "visceral pain is due to an abnormal increase in tension in the muscular element of the wall of the viscus," for a positive contraction is not the only cause of increased tension or of pain.

This conception of the cause of visceral pain can be equally well adduced in explanation of pains as diverse in character and circumstance, as those of labour, of gastric ulcer, of renal colic, and angina pectoris. But there are other observations accessory to the main conclusion which may be made in regard to the pains of visceral disease. These I shall summarize as concisely as possible, referring to them as "laws" of visceral pain for brevity and convenience, and implying thereby "present beliefs" rather than "unalterable truths."

#### "Laws" of Visceral Pain:

(1) Visceral pain has its origin in and is due to an abnormal increase in tension of the muscular element of the wall of the viscus, this increase in tension resulting either (a) from contraction of the muscle, or (b) from its failure to relax in the face of increasing intravisceral pressure. (Examples: (a) tonic spasm of the colon, (b) bladder pain in the early stages of retention before the muscle fibres have become overstretched.)

(2) Relieving factors in visceral pain, other than those which merely deaden consciousness, are invariably factors which reduce intravisceral pressure or encourage muscular relaxation. (Examples: the relief of pain from the sudden perforation of a diseased appendix; the passage of a calculus; the taking of food in duodenal ulcer; the administration of amyl nitrite in angina pectoris.)

(3) As would be anticipated if the truth of (1) and (2) is conceded, the severity of mechanically induced pain is in inverse proportion to the normal distensibility of the viscus. (Thus the most severe pains are found in disease involving tubes of small calibre and small distensibility, such as the ureter, the bile ducts, and the arteries; the more bearable pains in disease involving organs of wide calibre and a wide range of physiological distensibility and postural adaptability, such as the stomach and urinary bladder.)

(4) Visceral pain when occurring alone or dissociable from attendant pains in the somatic tissues or other viscera can be accurately located by the patient, the localization corresponding, not with any segmental nerve distribution, but with the surface marking of the viscus. (Examples: the loin gesture of renal pain; the sternal gesture of cardio-aortic pain; the accurate indication of the point of obstruction in oesophageal and some colonic strictures.)

(5) Visceral pain, having its origin in muscle, is related to the functional activity of the affected viscus. (Thus it is increased or relieved by food or fasting in gastric ulcer, by effort or rest in cardio-vascular disease, just as pain in skeletal muscle is aggravated by use and relieved by rest.)

(6) Referred somatic pain or soreness in visceral disease may accompany (a) severe visceral crises of mechanical origin, (b) inflammatory or ulcerative disease of the visceral wall, and more particularly if this involves the muscular coat. (Examples: (a) arm pain in angina and testicular pain in ureteric colic; (b) cutaneous soreness in appendicitis and chronic gastric ulcer.)

(7) Sustained somatic pain or soreness in visceral disease persisting apart from recent crises of visceral pain invariably implies inflammatory disease of the viscus in question. (Example: scapular angle pain and interscapular pain and soreness in chronic cholecystitis.)

(8) Conversely, absence of somatic pains and soreness is the rule in cases of visceral pain dependent on functional derangements or due to obstructive lesions in the more distensible viscera. (Examples: chronic colon spasm; pyloric or colonic growths.)

It need hardly be remarked that in actual practice we often encounter confusing effects which result from the extension of disease or multiple lesions or from the "spread" of pain due to temperamental factors or long-continued psychological or physical ill health. Such a qualification need not, however, damage these main conclusions. It would be impossible to detail here the accumu-

lated evidence on the basis of which it has seemed justifiable to formulate the foregoing "laws."

The referred sensory phenomena, requiring for their production special circumstances, such as intensity or prolongation through an inflammatory process of the appropriate stimulus, are infrequent in comparison with the local phenomena, and so are of less constant diagnostic value. It would therefore seem fitting to devote our attention more particularly to the primary visceral pains. It is chiefly with these that I shall concern myself in outlining the scheme for the analysis of a pain which follows.

#### THE ANALYSIS OF A PAIN.

When a patient comes to us with a complaint of pain it is customary and natural to ask him where the pain is felt and what its character may be. Each of us, no doubt, has his individual method of approach. Often a few direct questions and a little patience will elicit replies so informative as to put us immediately on the track of a reasonably accurate opinion, but there remain a host of "difficult pains" in which our simple routine brings no reward, and we are left "wondering," or are compelled to proceed to the physical examination, which may, in its turn, prove exasperatingly negative. Even the "further investigations," when we can indulge in such luxuries or send the case to hospital, do not necessarily supply the answer to our problem. It is just in these cases that we feel the need for some fuller method of inquiry. A little reflection will show that there are no less than ten reasonable questions which may be propounded in any given case of visceral pain, and, indeed, of most other kinds of pain. Each of these questions has some direct bearing on the qualities or circumstances of the symptom, and so renders our investigation less haphazard. It is true that the answers to these questions must be accorded very variable marks for merit. We cannot expect to obtain consecutive or intelligent co-operation from all our patients, but this is no reason for abandoning the attempt. For our failures to "establish contact" or to assess the reliability of replies we must hold ourselves at least in part to blame, and, profiting by them, must aim at an improved technique.

Of these ten questions two have a bearing on quality and quantity, and may be answered under the headings of (1) character and (2) severity. Three have a bearing on spatial relationships, and are answerable under the headings of (3) situation (including depth from the surface), (4) localization (or extent of diffusion), and (5) paths of reference. Three have a bearing on temporal relationships, and are answerable under the headings of (6) duration, (7) frequency, and (8) special times of occurrence. Two have a bearing on determining causes, and are answerable under the headings of (9) aggravating and (10) relieving factors. Over and above these questions directly relating to the pain our interrogatory must also include associated symptoms. All of these questions are concerned with the spontaneous pain experienced by the patient. At a later stage we proceed to examine for elicited visceral pain (or "tenderness") and elicited somatic pain (or "soreness").

#### Practical Applications.

Now let us consider the practical utility of an analysis of this kind. What can we learn of the character of a pain? It is common knowledge that certain descriptive adjectives crop up again and again in the language of our patients, and these must be accorded their full due. Thus the pain of ulcer is usually "gnawing" or of a dull "toothache" quality; it is sustained while it lasts—that is to say, it is not markedly fluctuating and never intermittent. In an acute irritative gastritis the pain may be peristaltic and intermittent. The secondary gastric pain of gall-stone dyspepsia is commonly of a "bursting" character. The pain of angina pectoris, sometimes so agonizing as to defy description, is often referred to as bursting, crushing, or vice-like. The pains of biliary and renal colic, devastating in their ultimate throes, are nearly always continuous and crescendo, and in no true sense "colicky"; they start with a dull ache which becomes progressively more intolerable. The pain of enteritis or small intestinal obstruction is truly "colicky"—that is to say, rhythmically intermittent,

sharp, and gripping while in action, but quickly giving place to ease between the spasms. "Burning" pains are rarely indicative of gross organic disease. The most familiar example is the homely heartburn, with its unpleasant, but never agonizing, sense of a retrosternal and almost "chemical" heat, although such evidence as we have suggests that it is, in common with strangury and tenesmus, an accompaniment of spasm. Diffuse abdominal burning sensations are chiefly encountered in depressed or emotional patients.

The severity of a pain is notoriously hard to measure. It is always well to discover from our patient at an early stage whether "pain" or "discomfort" is the more appropriate description. True pain is more likely to mean organic disease. Pains which are comparable with or worse than those of labour, or which in past episodes have required a hypodermic injection, we accept as genuinely severe. The effect of the pain on the performance of daily duties or mental work or equanimity or sleep allows some estimate of its gravity. Recourse to hot bottles, or bed, or analgesic drugs may help in our assessment, but in this part of our inquiry more than any other our own observational powers in regard to temperament or other factors likely to raise or lower the "threshold" of the individual to pain must be called into play.

The situation and localization of a pain are best determined by observing the patient's gesture, and, best of all, when the opportunity can be found, or made, to see him in its grip. The more defined and accurately localized the lesion responsible for a visceral pain the more accurate and defined, as a rule, is the gesture of the patient. There are many significant gestures. A famous proprietary pill has caught in its advertisements the typical gesture employed by the victims of a kidney stone. The pain of ulcer is commonly indicated with the tips of the fingers applied to mid-epigastrium; the pain of a functional dyspepsia with the flat of a roving hand. The point of arrest of a ureteric calculus may sometimes be shown with a single finger. In cases of chronic colon spasm I have seen the course of the colon accurately traced by patients wholly ignorant of anatomy. Among the best recognized paths of reference are those involving the left arm in angina pectoris, sometimes extending to the right arm, and in other cases usually confined to the inner aspect and reaching the elbow, the wrist, or even the ring and little fingers, and sometimes also rising to the neck or jaw; the scapular or interscapular pain (not shoulder pain) of gall-bladder disease; and the testicular pain of ureteric colic. Superficial and more often deep skin soreness may be of very real assistance in the diagnosis of gastric and duodenal ulcer, of some forms of appendicitis, of cholecystitis, and diverticulitis. Referred pain down the front of the thighs may accompany salpingitis and tubal pregnancy. The details of the search for zones of soreness have received full discussion in the literature and need not be considered here. Care is sometimes necessary to avoid confusion of a fibrositic tenderness with a true sympathetic hyperalgesia.

The duration of a pain has a very special significance, and may frequently throw light on the particular perturbation of function which the pain itself less surely expresses. Thus the intermittent pains of intestinal colic, so clearly due to peristaltic over-activity, last a few seconds only. The pains of an anginal seizure (excluding the sustained agony of coronary occlusion) rarely last more than a few minutes, and depend, we believe (whether their focus be in the heart or its vessels), on an inadequate relaxation—or adaptation of posture—on the part of the coronary plain muscle in response to increased cardiac work and a rising blood pressure. The pains of gastric and duodenal ulcer last an hour or more, until the stomach is empty or replenished. Biliary and renal crises may continue for an hour or hours, and often enough until the blessed relief of morphine has been won. In each instance we can nicely correlate the time character with the mechanical event.

The frequency and special times of occurrence of a pain are also instructive. Epigastric pain which recurs daily and with some constant time relationship to meals is almost certainly of gastric origin. Epigastric pain arriving at rare intervals, "out of the blue," and independently of

eating or other physiological exercise, should raise a suspicion of gall-stones or tabetic crises. Epigastric pain, absent at times of rest but immediately induced by certain efforts, is almost undoubtedly due to cardio-vascular disease. Of special times of occurrence it is also noteworthy that angina, in concert with other "spasmodic complaints," as observed by Heberden, has a predilection for the early hours of the morning after the first sleep. The hunger pains of duodenal ulcer often wake their victims between the hours of midnight and 2 a.m., and gall-stone pains at a somewhat later hour.

Among *aggravating factors* (taking again the better known types of pain) exertion, cold, annoyance, and particularly exertion after food, may all be provocative of anginal seizures. Jolting is apt to evoke pain in biliary, renal, and vesical calculus, and also in sufferers from chronic colon spasm, a disorder which is highly responsive also to the influence of cold, fatigue, worry, tobacco, and purgatives. Gentle thumping of the loin will more readily evoke the pain of calculous renal disease than simple deep palpation. Of *relieving factors* rest of body and mind and warmth are common to the majority of painful visceral disorders. Amyl nitrite has an almost specific effect in anginal pain, but not so in the status nigrus of coronary occlusion. Alkalis and belladonna (both probably by facilitating pyloric relaxation) have a well-known efficacy in gastric pain. Abdominal pressure, ill tolerated in inflammatory abdominal disease, may alleviate the pain of intestinal colic.

Now I would not for a moment have it supposed that an interrogatory such as I have outlined can be employed by every busy physician in every case of visceral pain with which he is confronted; but I would suggest that some such method is not only appropriate but essential if we are to prosecute a careful inquiry into any single type of pain; and further, that it may be of decided value in practice in elucidating what I have described as "difficult pains," and more particularly in those unhappily plentiful cases of chronic abdominal disease in which physical signs are scanty or altogether lacking. I can think of nothing better calculated to stay the epidemic of injudicious abdominal operations than an extension of interest in pain as a diagnostic symptom.

If I were asked to enunciate a few important principles for the everyday clinical study of pain my choice would fall upon the following:

First, in obscure cases and important decisions to try, whenever possible, to see the patient when his pain is present, for then and then only will his own observations be accurate and reliable, and not dependent upon memory, and physical signs, absent at other times, may be in evidence. We all know how few and far between (especially in consulting and hospital practice) are these opportunities of seeing our patients in pain. This circumstance alone is evidence of the rarity of continuous pain (excepting in advanced inflammatory and malignant disease), and supports the contention that visceral pains come and go in a physiological sequence and in obedience to physical laws.

Secondly, to pay particular attention to the patient's gesture, and, if he makes none spontaneously, to ask for a manual demonstration with the clothes removed. "A pain in the stomach" may mean a pain anywhere between the manubrium sterni and the symphysis pubis, and our endeavour must ever be in the direction of greater precision. I have several times seen the mistake made of supposing a pain to be gastric because it was related to food. Colonic pains may also be influenced for better or worse by food, but they are situated in the lower abdomen, whereas gastric pains are always epigastric.

Thirdly, to remember the close association which exists between visceral pain and the functional activity of the viscera in question. I once had a case referred to me by a cardiologist on a suspicion of stomach trouble with a request for a gastric analysis. The patient was an elderly man complaining of high epigastric pain after food. Before examining him I ascertained that the same pain was also evoked by walking, and that the case was undoubtedly one of angina pectoris.

It remains for me to cite from my personal store a few case histories which serve to show the value of a full

analysis of pain, and how such an analysis may lead to a more correct opinion or may modify judgement or treatment in important ways. I have been careful to include mistakes of my own as well as those of others. How often these mistakes give us insight into matters previously debatable or obscure.

[Case histories illustrating the following conditions were here recounted, the detailed descriptions being omitted owing to lack of space.]

(1) A case in which examination of the patient during an attack of pain altered a diagnosis, based on careful investigations, from duodenal ulcer to gall-stones.

(2) A case in which the severity of the pain led to a diagnosis of gall-stones and a fruitless operation; in which a radiologist later found a lesser curvature ulcer; but in which the clinical analysis led to a diagnosis (proved at a second operation) of "chronic posterior duodenal ulcer adherent to the pancreas."

(3) A case of chronic colon spasm previously diagnosed as (a) gastric ulcer, (b) renal colic, and leading to laparotomy.

(4) A case of chronic right-sided colon spasm for which appendicectomy was performed.

(5) A case of aortic disease with abdominal angina subjected to investigations of the alimentary tract.

(6) A case in which opinions as diverse as coronary arterial thrombosis and gall-stones were entertained by different observers.]

#### CONCLUSION.

It is a criticism sometimes levelled at the clinician that his work is regrettably unsystematic. In general the criticism may seem justified, and we know well enough that we cannot make of medicine an exact sort of science. But in particular it is indisputable that a careful clinical examination or inquiry is just as much a scientific procedure as any other measure of research. According to Huxley's definition, "Science is nothing but trained and organized common sense"—a definition which we should be very ready to accept, and which applies particularly well to clinical work.

We hear much talk at the present day of research in general practice. I marvel at the temerity of anyone who can suggest that the busy practitioner should add another burden to his arduous life; but if there is one way of research not involving too great a consumption of time, and open alike to the general practitioner or to any other branch of the profession, it is that of keeping very full clinical notes on selected cases with a view to the solution of a selected problem in symptomatology. No symptoms better lend themselves to such a process of inquiry than some of the common pains of daily practice. A series of cases of headache, backache, or abdominal pain, as fully investigated as circumstances will permit, and carefully followed through the years, will certainly provide individual rewards for their investigator, and may ultimately furnish the material for a reasoned contribution to morbid physiology. System and patience are necessary, together with an inquiring mind. The only essential apparatus for the research is a good card index.

## GANGRENE FOLLOWING THE USE OF ERGOTIZED RYE BREAD.

BY

WALTER J. DILLING, M.B., Ch.B.,

ASSOCIATE PROFESSOR OF PHARMACOLOGY, UNIVERSITY OF LIVERPOOL,

AND

R. E. KELLY, C.B., M.D., B.Sc., F.R.C.S.,

PROFESSOR OF SURGERY, UNIVERSITY OF LIVERPOOL.

EARLY in 1923 we reported at the Liverpool Medical Institution a case of gangrene in symmetrical toes, a condition which followed upon a diet of ergotized rye bread.<sup>1</sup> In view of the recent article in this *Journal* describing symptoms, resembling those of ergotism, among foreign Jews in the Manchester area,<sup>2</sup> a synopsis of the essential features of epidemic ergotism and of this case of gangrene will now have greater interest.

Although the ergot fungus (*Claviceps purpurea*) occurs most commonly in rye, it occasionally infects wheat, oats, and barley, and, failing its usual host, it can exist on the following grasses: Poa, Phleum, Anthroxanthum, Agrostis,

Elymus, and others. The conditions favourable to propagation are a poorly cultivated or damp, clayey soil, and a wet season, together with the presence, at the borders of the field, of grasses which can harbour the fungus. The chief active principles of ergot have been proved by Barger, Dale, and others to be the alkaloids ergotoxine and ergotamine, and the amine bases tyramine and histamine.<sup>3</sup> Ergotoxine, which stimulates the peripheral motor sympathetic mechanism, causes the arterial constriction which, when prolonged, results in gangrene; excessive doses of ergotoxine paralyse the myoneural junctions of the motor sympathetic endings; tyramine, like adrenaline, stimulates both motor and inhibitory sympathetic receptors; and histamine, which is a direct stimulant to involuntary muscle, causes, as is well known, a large fall in blood pressure.

Ergotism may be of two types—the convulsive and the gangrenous. The former predominated in epidemics in Germany, Russia, and Eastern Europe; the latter in France and Switzerland.

The onset of the convulsive type is characterized by malaise, dizziness and headache, nausea or vomiting, colic with chronic diarrhoea, and cold extremities—symptoms of small diagnostic value. The more characteristic symptom of formication begins in the fingers and toes, and may spread to the body. Severe cases exhibit gastro-enteritis with muscular twitchings or painful clonic and, later, tonic contractions of different muscles, while, finally, contractions, chiefly of the flexor muscles of the limbs, may result.

The gangrenous type may exhibit similar initial symptoms; then follows, after intervals varying from a few days to several weeks, great pain with an erysipelas-like reddening of the skin and swelling in some peripheral part. This gives place to pallor and anaesthesia, cyanosis, darkening of the part, and the appearance of gangrenous blisters with separation of the epidermis; a sharp demarcation line generally results.<sup>4</sup>

From a study of the epidemics it appears that some individuals are more sensitive to ergot than others; thus instances are noted where some members of families eating the same ergotized bread remained unaffected or mildly affected while others were severely poisoned.<sup>5</sup> The time of appearance of gangrene is also uncertain; it is stated to have occurred four days after the consumption of the ergot,<sup>6</sup> or may be delayed for a month, or perhaps occur after consumption has ceased.<sup>7</sup> Some of these last cases appear doubtful, although Kobert recorded delayed poisoning in animals.<sup>8</sup> Both Kobert and Grünfeld noted in Russia that epidemics occurred shortly after harvest time, and generally in years following a preceding bad harvest, which caused the people to eat the new season's rye shortly after it had been reaped. Grünfeld also showed that ergot kept in a dry room lost activity by one-half each two months succeeding the harvest.<sup>9</sup> The proportions in rye which have caused epidemics vary from 1 per cent. in the Poltova, Kursk, and Tomsk epidemics<sup>10</sup> to 7 per cent. in the Novgorod epidemic (1879) and more.<sup>11</sup> Ergot in doses of 0.2 gram daily for one month has been stated to cause gangrene two months later,<sup>12</sup> and 1 gram daily induced intestinal symptoms in a few days,<sup>13</sup> while Lehmann regards 0.2 per cent. and upwards as likely to be injurious proportions in man.<sup>14</sup>

The following is the clinical record of a man, aged 42, a Polish Jew, by trade a travelling salesman, who had lived in England for thirty-five years.

He was admitted to the Royal Infirmary, Liverpool, on November 9th, 1922, complaining of pain and discoloration of the second toe of his left foot. He stated that he noted first some numbness in the toe, which later became red and finally black. The process was slow and occupied some five weeks. His history revealed that the same toe on the opposite foot had been amputated twelve months previously for an exactly similar condition two or three months after the first appearance of a discoloration.

**Condition on Admission.**—The terminal phalanx was obviously gangrenous and quite dry, but showed no definite line of demarcation; the toe was very painful, especially at night. There was no arterio-sclerosis, diabetes, or renal disease, and, although it was impossible to feel pulsation in either the anterior or posterior tibial artery, the radial arteries were not unduly palpable or thickened. There was no apparent disease of the heart, and the systolic blood pressure—taken after operation—was 140 mm. of mercury. Either thrombo-angitis obliterans or Raynaud's disease seemed the obvious diagnosis, but there had been no preliminary spasm of the arterioles. When asked what kind of bread he ate, he stated that

he always ate black or rye bread, known as "Kosher" bread. At the amputation of the second toe on November 17th there was an extraordinary lack of bleeding, but the wound healed well without further gangrene. The patient was seen on January 20th, 1923, and was well except that the circulation was still somewhat sluggish, although he had then given up rye bread for two months.

**Pathological Report.**—Dr. W. Howel Evans, lecturer in pathology, Liverpool University, reported as follows: The arteries of largest calibre, at the level of the first phalanx, show well-marked medial hypertrophy without calcification, and considerable regular, diffuse, intimal thickening and *ante-mortem* thrombosis; in one of them the clot is well organized and partly canalized. There is a very slight degree of fibrosis of the adventitia. In sections cut at the level of the second phalanx the more distal vessels show less marked changes, consisting, chiefly of a moderate degree of intimal thickening, sometimes irregular and without thrombosis. In this region the muscle is largely necrotic, no definite changes are observed in the arterioles or the nerves, and there does not appear to be any gross alteration in the veins.

A specimen of the rye bread usually eaten by this patient was examined microscopically and revealed mycelial tissue, which, in chloral hydrate solution, exhibited the oil globules characteristic of ergot. An extract was prepared with 60 per cent. alcohol acidified with citric acid; it was purified with absolute alcohol, and the residue, after evaporation, was dissolved in water. This extract, in doses representing 88 and 46 grams of bread, injected intramuscularly into a white Leghorn cock, produced after an hour distinct cyanosis and blackening of the back part of the comb and marked pallor of the anterior borders of the wattles.

With the assistance of Dr. W. Hanna, deputy medical officer of health, Liverpool, we found that samples of the flour also contained ergot tissue, and that, in the rye at the mill, ergot was obviously present. One sample picked over showed 0.1 per cent. by weight adulteration with pure ergot, and, in addition, many of the rye grains were blackened and microscopically revealed mycelium. In our opinion 0.1 per cent. represents the minimum of adulteration, and, from the relative frequency of mycelium in the first loaf, we surmise that the adulteration before our inquiries were broadcast was probably greater. We were informed that the rye flour was partly diluted with wheat flour by the baker, but he was vague about the exact proportion of the admixture; microscopical examination indicated that it was approximately one-half. As a precautionary and prophylactic measure the medical officer of health gave instructions for the dilution with wheat flour to be increased.<sup>15</sup>

It was ascertained that the rye had been grown in a comparatively restricted area of Lancashire; the farmer was quite well aware that his rye was infected, and, since 1922 was a wet year, it was presumably more heavily infected than usual. This patient, however, had suffered from gangrene a year previously, and it may be that in this area the relative infection shows merely seasonal variations.

Samples of the pure ergot taken from the rye were extracted, and when the extract was added to the isolated virgin guinea-pig uterus suspended in Tyrode's fluid it produced powerful contractions of the uterus in doses representing 0.02 gram of ergot.

An important warning must here be emphasized—namely, that this pharmacological test is fallacious and misleading if it is performed with the rye bread or an extract prepared from it, because certain cereals and starches contain a principle which induces powerful uterine contractions, but instead of causing, like ergotoxine, a rise in blood pressure, it induces a very marked fall—actions resembling those of histamine. This was noted by Macdonald and Grier<sup>16</sup> in testing the rye in Manchester. Our investigations showed that this uterus-contracting principle was present in wheat, oatmeal, maize, rice, and potato in variable amounts, and in their starches, but it was not present in specimens of chemically pure Lintner's starch. By various methods, such as that of Kutscher,<sup>17</sup> attempts were made to isolate the pure principle. It was found that concentrated extracts produced a decided red colour with Pauly's diazobenzene reaction, which is given by both tyrosine and histidine, and also with Totani's reagent,<sup>18</sup> which is believed to be characteristic of histidine, but it has not been possible to prepare either a crystalline picrolonate or picate, and, by determining the melting point of the salt, to identify finally the principle with histamine. The pharmacological actions and colour tests make it probable

that it is histamine or a nearly related substance, and that our inability to obtain other than an amorphous picrate may be due to some impurity.

The chief difficulty is to distinguish this case from Buerger's thrombo-angiitis obliterans, which affects usually the lower limb of a male between the ages of 30 and 40, and may recur in the other limb later. As Buerger<sup>1</sup> and Parkes Weber<sup>2</sup> have shown, this disease is common among Jews, but it is not confined to this race.<sup>3</sup> Evidence has been adduced to suggest an organismal<sup>4</sup> and also a nicotine<sup>5</sup> etiology.

We delayed full publication of our knowledge because we were not satisfied that our isolated case could be ascribed solely to ergot poisoning, and we should similarly hesitate to accept as proofs of ergotism evidence of numbness and coldness in the extremities of Jewish tailors, whose working attitude involves popliteal compression and whose workrooms may be cool. Since careful inquiries by Dr. W. Hanna, the deputy medical officer of health, in 1923, and again recently, failed to reveal other cases exhibiting symptoms of ergotism amongst foreign Jews in the Liverpool area, the presence of 0.1 per cent. of ergot in rye has not been proved dangerous, and we must regard our case either as a sporadic one of idiosyncrasy to gangrenous ergotism, or as a case of slight thrombo-angiitis obliterans contributed to by a diet containing ergot, for the following reasons: (1) the man ate exclusively rye bread containing at least 0.1 per cent. active ergot; (2) his attacks occurred in succeeding Novembers, about two months after the fresh ergotized rye was milled; (3) the absence of general arterio-sclerosis and diabetes;

(4) if 0.2 gram of ergot daily be regarded as causing gangrene this man would have taken this amount in three-quarters to one pound of rye bread; (5) cases of thrombo-angiitis obliterans usually involve the larger vessels of the limbs, whereas our case was peripheral and circumscribed.

NOTES ON THE INJECTION TREATMENT OF  
VARICOSE VEINS.

BY

H. M. HANSCHALL, D.S.C., M.R.C.S., L.R.C.P.,  
D.T.M. AND H.,HONORARY MEDICAL SUPERINTENDENT AND MEDICAL OFFICER IN CHARGE  
OF VENEREAL DISEASE CLINIC, SEAMEN'S HOSPITAL, ROYAL  
ALBERT DOCK.

THROMBO-PHLEBITIS and peri-phlebitis of a varix sometimes occurs during or very soon after a toxic fever, such as typhoid fever; and also after a direct blow on the varix; fibrosis and cure of the varix follow. The preceding phlebitis, however, has usually been treated with alarmed respect and lengthy rest in bed.

Recently, I met with a traveller who, during a mild typhoid fever, developed phlebitis of the varicose veins in one leg. He rejected advice to remain in bed, and with a thick solid red tender vein from ankle to saphenous opening took a four weeks' journey home—and then permitted me to reproduce by injection-stages a very similar clinical condition in the varicose long saphenous vein of the other leg.

It has been noted that phlebitis of a normal vein is set up sometimes by its intravenous injection with arsenobenzol compounds, quinine salts, or echaumoogra oil derivatives. In my experience this has been transient with the first two drugs; the oil derivatives more easily cause fibrosis and occlusion of the healthy vein.

In 1913 in West Africa, unable to find an arm vein in a fat alcoholic patient suffering from subtertian malaria with cerebral symptoms, I had recourse to a visible varix in his leg; 10 grains of quinine hydrochloride in 10 c.cm. of boiled rain water were injected into the varix, and the leg then lifted high. This produced thrombo- and peri-phlebitis. He survived to express satisfaction for the cure of the varix. Some time later I injected salvarsan into a varix in the leg of another patient, being foiled of an arm vein; cure of the varix resulted after thrombo-phlebitis and fibrosis. Such an experience led, with trepidation, to some "cures" of varicose veins with quinine injections until, after the war, Sicard's work brought encouragement to proceed less fearfully and sporadically.

During the last few years I have treated over 200 cases of varicose veins of the leg by injecting into the varices quinine hydrochloride, sodium salicylate, or sodium

chloride. In over 100 the quinine salt has been used. In my hands, of the three, it has been the least uncertain in effect.

Recently, with Dr. J. C. Gilroy, some observations were made on a perhaps callous, but consenting and rewarded male patient in the Seamen's Hospital, Royal Althorpe Dock who had many varicose veins in both legs. About two inches of uninjected varix were dissected out for control comparison; and also, at intervals of time, the same length of other varices, ten to fifteen minutes, twenty-four hours, and seven days after their intravenous injection with one or other of quinine hydrochloride 13 per cent., sodium salicylate 20 per cent., and sodium chloride 20 per cent.

Naked-eye and microscopic examination of the several injected varices revealed, ten to fifteen minutes after injection, no clot and no recognizable change in vein wall; twenty-four hours after injection, however, the lumen was filled with firmly adherent clot, the intima was swollen, with damaged cell nuclei, and there was round-cell infiltration of the tissue outside the vein. Seven days after injection the firmly adherent clot was undergoing organization.

The treatment has had its difficulties, tediums, and anxieties for patient and operator. I have found, as compared with many thousand injections into normal arm veins, that only the larger varices are easy to inject. In most cases the patient must stand to be injected. For the operator's convenience this standing must be on a level considerably higher than that of the floor—a severe trial for the nervous patient; all are nervous at first, and some always. Often the patient may sit high enough to suit the operator; very rarely can injection of a varix be performed with the patient lying down. A tourniquet above the varix helps not at all, one below it sometimes helps a very little.

The more advanced the varicose condition the less uncertain is the effect of the injected drug; but intensity of effect may vary in the same leg, with apparently the same size and condition of varix, and same dose of same drug. Sodii salicylate 20 to 30 per cent., sodii chloride 20 per cent., and quinine hydrochloride 13 per cent.—each sometimes has failed after more than one injection into a varix to produce the requisite obvious phlebitis. With each the thrombo-phlebitis and peri-phlebitis has sometimes extended quickly far beyond the usual one or two inches of vein above and below the point injected.

This incommodes the patient, and may even cause a preference for a few days in bed. The operator's anxieties do not count.

In tropical medicine quinine injections, subcutaneous or intramuscular, have had an occasional horrid reputation for producing sloughing cellulitis, deep abscess, and, in the tropics, have been followed more than once by a fatal tetanus. It has also been reported that sodium salicylate 20-30 per cent. and sodium chloride 20 per cent., injected under the skin, have caused sloughing. Another kind of slough, one-eighth to one-half of an inch in diameter, has, under my hands, been produced by each of these three drugs, although the lumen of the varix had been fairly entered. This slough has occurred where loops of smaller tortuous varicose vein lay closely together; it appeared one-half to three-quarters of an inch above the point injected; injections were directed upwards. It is true that to transfix a loop in such a varix bunch is easy. In these cases, however, injection was accurately intravenous, and there was no haematoma or subsequent discoloration of skin from extravasated blood.

The clinical events have been: A purplish mark in skin; next day this was a grey blister, which later dried to a hard adherent black scab surrounded by inflamed and tender skin. Some weeks later the scab could be separated, disclosing then an excavated pouch filled with black sticky clot, under which lay small grey-yellow sloughs. Microscopic examination of clot and sloughs revealed no organisms, and none has grown from clot or slough in aerobic culture. It is evident that a whole small length of thrombosed varix, with some of the skin over it, died quickly *in situ*. Healing readily followed on treatment with hypotonic salines. But the patient's view of the matter may be as black as the scab, and in one it was almost a jet-black ingratitude; such patients do exist.

This sort of sloughing, and the far extension of thrombo- and peri-phlebitis, appear in retrospect to have been due to too large a dose of the drug for that particular varix. Both were infrequent, and have not occurred with more cautious dosage. In none of the cases, even in those with a rapid extension of the phlebitis from lower leg to saphenous opening, has there been noted any rigor or fever—both usual features of a *septic* thrombo-phlebitis.

In hospital out-patients varicose ulcers of leg have healed well after the injection of the accompanying varicose veins. In three women in the third to fourth month of pregnancy cure of varicose leg veins by injection into them of quinine hydrochloride produced complete relief from aching legs and oedema of ankles, and no hint of relief from the pregnancy. Even doctors have submitted to injection of their leg varices. One or two have lessened the tedium of treatment by probing discussions of the symptoms and signs of embolism. There has been no demonstration of embolism; and in view of the large number of cases now safely injected here and in France, by many practitioners, the risk of embolism appears to be remote.

Thrombo-phlebitis of a vein, whether caused by bacterial toxin, trauma, or "chemical" injection, is, then, safe—if the thrombo-phlebitis is *aseptic* and the vein *varicose*. The dose of quinine hydrochloride 13 per cent. (with methane as analgesic) has varied from a few drops to—very rarely—1 c.cm. But even large loops of varix, if lying closely together, should receive small doses. It is easier to repeat an injection next time than to treat a slough ulcer. The most frequent dose has been 1/4 c.cm.—and four injections at a sitting.

It has been almost the rule for patients to return later (some with shorter skirts and some with now one stocking only—a thinner one—on each leg) to demand injection of some small veins not thought worthy of treatment when the bolder varices had challenged operator and patient; some, too, to deplore once more the scars of a past excision of veins that had not prevented varices reappearing. Perhaps a few of these vain scalp scars can be cancelled out by the depressed pigmented scar of an injection slough, or in some cases by the pale snuff-coloured sinuous line, or the brownish patch, that marks the track of a past too acute injection peri-phlebitis. Still later, the varices, now completely forgotten, and represented only by a thin hard subcutaneous cord; this more or less beige staining may

be counted to the operator for unrighteousness. It is not unlikely that the stain will prove as permanent as the scalp and the slough scars. Two of the earlier patients in this series have now all three, yet are content and even grateful to all concerned; such patients do exist.

## THE TREATMENT OF HYDRONEPHROSIS.

BY

C. C. HOLMAN, M.B., B.Ch., F.R.C.S.,

HONORARY SURGEON, NORTHAMPTON GENERAL HOSPITAL.

In general surgical practice hydronephrosis is met with somewhat infrequently. It so happened that during the year 1927 six cases came under my care, of which five appear to me to present features of sufficient interest to justify publication. The sixth was a simple case of impacted renal calculus.

### CASE I.

On January 16th, 1927, I was called to see in consultation a farmer, aged 79, wiry and active, with a tendency to occasional over-indulgence in alcohol. About fourteen days earlier he first complained of abdominal pain and nausea, but no vomiting. Under medical treatment the pain subsided for a few days and then recurred, with abdominal distension and constipation. The abdomen was found to be distended, but there was no visible peristalsis. Rectal examination revealed prolapsed piles, from which he had suffered for many years, and enlargement of the prostate. No growth could be made out. He was removed to a nursing home. Under treatment by enemata his condition improved and an x-ray examination after an opaque enema was carried out. The enema was badly retained and did not go beyond the lower end of the sigmoid. Everything seemed to point to obstruction due to growth, and an operation was decided on.

### Operation.

On January 20th an incision was made, splitting the left rectus below the umbilicus. The sigmoid was found to be normal except for some small diverticula. On passing the hand upwards a large hydronephrosis of the left kidney was at once found. The right kidney felt normal. The abdominal incision was closed and the patient turned on his right side. A free lumbar incision was made. The pelvis of the kidney was found distended to a capacity of some thirty ounces; it was very adherent to surrounding structures. The fluid was evacuated by puncture, and the kidney, together with as much of the pelvis as possible, was removed rapidly. A small tear of the peritoneum was sutured and the wound closed, except for a drain.

The patient bore the operation well. He had to be catheterized the next day, but subsequently passed urine without trouble. He was well enough to leave the home three weeks after the operation, although there was still some discharge at the site of the drainage tube.

The case is interesting from the point of view of diagnosis. Dilatation of the renal pelvis not infrequently gives rise to symptoms of intestinal obstruction. In this case the tumour was masked in the first instance by abdominal distension. The probable explanation of the misleading x-ray findings is that the prolapsed piles prevented proper retention of the opaque enema. The urine was normal. The operation had to be carried out rapidly, and no cause for the hydronephrosis was found. There was not sufficient prostatic obstruction to affect the right kidney.

### CASE II.

A medical student, aged 20, had been subject from early childhood to attacks of pain in the left loin, accompanied by vomiting, and lasting between one and eight days. The pain rose gradually to a climax and as gradually passed off. No diuresis after an attack had been noticed. On one occasion bacteriological examination of the urine had been made and streptococci found. The attacks had become more frequent lately and had interfered with his studies. He had been treated for gastritis, an x-ray examination of the stomach had been made, and he had also undergone a course of psychotherapy. Three months prior to my seeing him an x-ray examination of the kidneys had been made elsewhere, and he had been subjected to cystoscopy, after an attack was over, with negative results.

The patient was admitted to the Northampton General Hospital, and I was fortunate to see him during an attack. He was in considerable pain, and very tender on palpation in the left costo-vertebral angle. He had vomited copiously. The abdominal wall was rigid and muscular, and no tumour could be felt. A little pus was present in the urine. Immediate cystoscopic examination was carried out under general anaesthesia, after an injection of indigo-carmin. There was free excretion of the dye by the right kidney, but none by the left. A catheter passed up the left ureter stopped at 25 cm. A diagnosis of intermittent hydronephrosis was made.

### Operation.

On February 4th, 1927, a lumbar incision was made, and the left kidney was found much enlarged and reduced to a shell. The pelvis was dilated to a capacity of seven or eight ounces. Any

sort of plastic operation seemed out of the question, so nephrectomy was performed. The lumen at the uretero-pelvic junction was found to be very small. Recovery was rapid.

The history in this case was typical of that of intermittent hydronephrosis. There was presumably a congenital stricture at the uretero-pelvic junction. When secretion of urine was free the pelvis would become distended, with consequent valve formation at the orifice and increased obstruction to the passage of urine. Had the condition occurred on the right side a diagnosis of appendicitis would probably have been made sooner or later. The previous negative cystoscopic findings were presumably due to the fact that the examination was made when the attack was over. A pyelogram might have settled the diagnosis.

#### CASE III.

A married woman, aged 53, was seen in consultation on account of haematuria. She stated that she had passed blood on one occasion seven years previously. When recovering from influenza in February, 1927, she had profuse haematuria lasting several days, accompanied by pain in the right loin. She was a very thin woman, and the right kidney was palpable and tender. She was admitted to hospital. Cystoscopy on February 4th, 1927, after injection of indigo-carmin, showed active excretion of dye by the left kidney. The right ureter excreted a little turbid urine, but no dye. The patient was then anaesthetized, and the right kidney exposed by a lumbar incision. The kidney was found but little enlarged, the cortex was thin and its surface lobulated, the renal pelvis was dilated. The kidney was removed and found to be full of blood clot. No cause for the bleeding or for the dilatation of the pelvis could be found. The patient made a rapid recovery.

Haematuria as a symptom of hydronephrosis is recognized, but is rare. Prior to operation a diagnosis of new growth was made, although the history of haematuria seven years previously was difficult to account for on this diagnosis.

#### CASE IV.

An agricultural labourer, aged 52, had noticed a swelling in the lower abdomen for about three months; for a fortnight prior to admission it had been somewhat painful. He was a spare, muscular man. In the lower abdomen was a large cystic swelling, the centre of which was somewhat to the left of the mid-line. Cystoscopy showed the right ureter to be functioning normally, while from the left came a little blood-stained fluid. A diagnosis of hydronephrosis of an abnormally situated left kidney was made.

#### Operation.

The abdomen was opened through a left paramedian incision below the umbilicus. The right kidney felt normal. The posterior parietal peritoneum covering the tumour was incised, the swelling tapped, and six pints of chocolate-coloured fluid evacuated. The very large hydronephrotic kidney was removed without trouble and the posterior parietal peritoneum closed, leaving room for a drainage tube. The patient made a rapid recovery.

The diagnosis of what would otherwise have been an obscure condition was made easy by cystoscopy. The abnormal situation of the kidney made a transperitoneal removal the operation of choice, and it gave opportunity to examine the right kidney. With a normally situated kidney a loin incision should, in my opinion, always be employed.

#### CASE V.

A young married woman, four months pregnant with her second child, was sent into hospital as an urgent case about 8 p.m. on December 2nd. At 3 p.m. on December 1st, after a good meal, she complained of pain in the lower abdomen and vomited. During the night she vomited slightly, and was unable to sleep owing to the pain. She stated that for some years she had been subject to occasional attacks of pain in the right loin.

On admission she looked ill, the temperature was 100° F., and pulse 130. The tongue was clean and she was very tender in the right loin and in the right iliac fossa. The pregnant uterus interfered with palpation. The urine was normal. She was not thirsty and micturition was not frequent. Vaginal examination did not help. It was thought that pyelitis could be excluded. The diagnosis seemed to lie between acute appendicitis and some renal condition. The patient was very ill and operative intervention obviously urgent. The most practical method appeared to be to open the abdomen and, if nothing abnormal was found therein, to expose the right kidney.

#### Operation.

The abdomen was opened through a right paramedian incision below the umbilicus. A little free fluid escaped. There was no inflammation of the appendix. The gall-bladder and left kidney felt normal. The right kidney could not be felt, but there was a diffuse swelling in the right loin behind the peritoneum. The wound was closed, the patient turned on her left side, and an incision made in the loin. Much blood-stained fluid was evacuated, and a sacculated kidney could be felt lying high up under the ribs. On delivering it a hole in the cortex was seen, through which fluid was still escaping. The kidney was removed and the wound closed with drainage. A large stone was found blocking the

pelvis of the kidney. Spontaneous rupture of the thinned-out cortex appeared to have taken place. The patient made a good recovery and did not abort.

Spontaneous rupture of a hydronephrotic kidney must be a rare event. The onset of pain in the lower abdomen was an interesting feature. It is a debatable point whether I should have opened the abdomen, but the patient was very ill, the hour was late, and cases of intraperitoneal rupture of a hydronephrosis are on record, so the procedure seems to have been quite justifiable.

## TREATMENT OF GONORRHOEA IN WOMEN BY SWABBING WITH MERCUROCHROME AND FLAVINE.

BY

R. S. S. STATHAM, O.B.E., M.D., CH.M.,

HONORARY GYNAECOLOGIST, BRISTOL ROYAL INFIRMARY; ASSISTANT  
MEDICAL OFFICER, BRISTOL VENEREAL DISEASE CENTRE.

EVERY gynaecologist who has to treat many cases of gonococcal infection of the female genital tract will agree that there is no more difficult condition to deal with adequately, and that any method whereby the time of treatment can be shortened is welcomed by patient and medical attendant alike. The method of treatment here described has been tried for the last nine months at the Bristol venereal disease centre, and the results are compared with those obtained from other methods. Although the total numbers are not large the results have been so encouraging that it seems worth while recording them in the hope that the method may be further tried out at other centres and in private practice.

The main points in the treatment of women suffering from gonorrhoea are daily and regular attendance, and treatment by a skilled and conscientious nurse or medical man, until cure is obtained; and the following factors are necessary in any treatment if good attendance is to be obtained.

- (a) Each treatment sitting must be fairly short.
- (b) The method used must cause as little discomfort as possible.
- (c) The patient must see some steady and increasing improvement in her condition.
- (d) There must be an atmosphere of sympathy and cheerfulness and complete absence of any suggestion of moral turpitude.
- (e) The treatment must be efficiently carried out.

It is claimed that this method of treatment completely meets conditions (a), (b), and (c). With regard to (d) and (e) the practical treatment in this clinic is carried out by the sister and her nurses, and any success achieved must be attributed to their enthusiastic co-operation and careful attention to detail. Not only have they reduced the discomfort of the patient to a minimum, but they have established a cheerful confidence, which is the first essential in getting the patients to attend regularly.

In this paper no mention is made of the ordinary methods of complete pelvic and bacteriological examination carried out on each patient.

#### Criteria of Cure.

Three consecutive negative smears from the cervical canal and urethra are taken at a month's interval, each after a menstrual period, and a culture from both situations. During these nine weeks no treatment at all is given. A "final test" is taken in a similar manner three months later. It will be seen that the patient has been five months later without any treatment when the "final test" is taken. If any of these tests are found positive a month's treatment is given and the series is started again. In every case of gonorrhoea two Wassermann blood tests were performed, the second following a provocative dose of 0.3 gram of stabilaran.

#### Methods of Treatment Previously Used.

Of the many methods devised the following has up till recently been found by far the most satisfactory, and is known here as "Routino A." It is a modification of a method described by its originator, Colonel Harrison, in

the *British Journal of Venereal Disease* (January, 1926). Briefly, it consists in irrigation of the urethra and cervical canal with a solution of sodium chloride and chloramine-T, and then packing the vagina with gauze soaked in glycerin of borax, or glycerin of ichthyol, or glycerin of eucalyptus daily for successive weeks.

While this method of irrigation undoubtedly clears up the surface of the cervix and vagina with great rapidity it fails in that it does not enable the fluid to reach all the folds and pockets of the vagina. The fornices retain small pools of infected material, and the vagina being H-shaped in section is not fully distended by the flow from the Harrison's two-way nozzle. It seems to be very necessary that a daily complete cleansing of the whole area accessible should be performed. The packs, while distending the vagina and keeping the glycerin in contact with the walls, unfortunately act as corks to the cervical secretions, and it is surprising how much muco-pus is found pent up behind them when they are withdrawn. Undoubtedly the associated chronic cervicitis is not improved by the prevention of exit of the quantity of fluid exuded in the presence of the glycerin.

#### The Method under Consideration.

The patient is placed in a gynaecological examination chair and the vagina is washed out with a weak solution of boric acid (mercurochrome acts best in a mild acid medium). A fenestrated Cusco's speculum, as large as can be tolerated, is then introduced and the vagina and fornices are fully stretched. All muco-pus is now cleared away with the boric lotion, and then a swab, soaked in 1 per cent. mercurochrome, is rubbed all over the cervix and vagina, so that the solution reaches every part, including the orifice of the cervical canal. As most cases display some urethritis at the beginning of treatment a small quantity is run into the bladder, retained there for a few minutes, and then passed again. The speculum is removed and the treatment is now ended.

In cases in which the gonococcus seems resistant to mercurochrome a change is made by using 1 in 1,000 flavine for seven days in exactly the same way, and then reverting to the mercurochrome.

#### Comments.

This method of treatment is rapidly and easily carried out, but entails care and some practice on the part of those performing it. It is absolutely necessary that all parts of the vagina be fully distended and swabbed over, and that no pockets are left untreated. It allows free drainage for all cervical secretions and causes no irritation to the inflamed surfaces. Mercurochrome, in an acid medium, penetrates to a remarkable extent, and the immediate result is a clearing up of the offensive discharge, with a consequent encouragement of the patient. Since using this method of treatment there have been practically no instances of patients failing to attend regularly and complete the treatment, though many of them have to come considerable distances for their daily swabbing.

#### Results and Comparisons.

Forty consecutive cases were treated daily except during the menstrual flow. (A few patients missed one or two treatments.) In all cases the gonococcus was present at the beginning of treatment.

	Days.
Average number of days from the beginning of treatment till the first negative smear* was obtained	39.1
Longest period under treatment (one case)	100.0
Shortest period under treatment (one case)	4.0

\* First negative smear is taken to mean the first smear of the final series. If a positive smear occurred afterwards the whole series was started over again.

Leaving out the extremes at both ends, it was found that twenty-eight days sufficed to render the smears negative in most cases.

Twelve cases were treated for one or two weeks with flavine 1 in 1,000 in place of mercurochrome.

	Days.
Average number of days under treatment	45
Longest period under treatment	91
Shortest period under treatment	17

*Complications.*—The above fifty-two cases include one case of acute gonorrhoeal rheumatism of the wrist-joint, which cleared up very rapidly, and two Bartholin's abscesses, which were incised as complete removal was impossible.

*Failures.*—Two cases have failed entirely to respond to treatment and have also made no progress with routine treatment. In both cases there is a possibility of frequent reinfection, one case being a prostitute, while the other has a husband who will not undergo treatment, although he is infected.

It will be seen that by this "swabbing" method there is a reasonable chance of getting the first negative smear in about a month, while the patients' symptoms have usually vanished some two weeks earlier, and they feel correspondingly encouraged. As soon as a negative smear is obtained active treatment is stopped till after the next menstrual period, and the patient need not attend again, till that date, when she comes up for smears and cultures only.

#### Comparison with Cases Treated by Routine A.

Fourteen cases, treated by Routine A during the same period, were taken as control cases. They were not selected cases, being the first cards which came to hand of those patients who had attended regularly.

	Days.
Average number of days to first negative smear	153
Longest number of days to first negative smear	270
Shortest number of days to first negative smear	60

There were twenty-one cases in which treatment had been going on for over six months, but the attendance was not absolutely regular, and so they are not included in the above figures, as the comparison was not considered fair.

#### Cases Treated first by Routine A and then by Mercurochrome Swabbing.

These cases are perhaps the most interesting. Fifteen cases which had been under Routine A for some time were examined and smears taken with positive results. They were then put on to the mercurochrome treatment, with the following results:

	Days.
Average number of days under Routine A and still infected	111.2
Average number of days under mercurochrome to the date of first negative swab	28.2

In addition to these cases treated at the venereal diseases centre, I have found this a most useful form of treatment in private practice. Among others, there have been five cases of pregnancy treated. They all made an uncomplicated recovery and there was no ophthalmia amongst the infants. The only essential is the service of a good nurse, or personal application of the mercurochrome by the medical attendant.

#### Conclusions.

1. This method of treatment is efficient in that it appears to cure the disease.
2. It greatly shortens the time under treatment, and so is a sound economic factor, both for the patient and the venereal disease centre.
3. It is not in any way painful or unpleasant.
4. The rapid improvement in the symptoms is encouraging to the patient, and so regularity in attendance is promoted.

It is very probable that there may be other substances which will prove even more efficient than mercurochrome, and it is intended that a trial shall be begun at once of the solution of brilliant green and crystal violet, used by Messrs. Berkeley and Bonney as a vaginal disinfectant, this to be used in an exactly similar manner to the mercurochrome.

I have to thank Dr. S. Hardy Kingston, director of the Bristol centre, for his encouragement in the trial of this method and the transfer of numbers of his cases on Routine A for comparison; also the other medical officers of this clinic for their hearty co-operation, and the sister and nurses for their enthusiasm in carrying out the treatment and their interest in reporting the progress of the cases under treatment.

## Memoranda:

## MEDICAL, SURGICAL, OBSTETRICAL.

## VESICAL BILHARZIA: DOUBLE INFECTION.

Dr. H. FAIRBairn states, in a memorandum that appeared in the *British Medical Journal* of January 14th (p. 52), that he knows of only two previous references to the existence of double vesical infection of *S. haematobium* and *S. mansoni*. He suggests that such cases are commoner than is at present supposed.

In a paper published in 1926<sup>1</sup> I have recorded the existence of *S. mansoni* ova in the urine of no fewer than 56 patients. Of these, 48 had double infection with both parasites, and 8 had pure *S. mansoni* infection of the urinary tract. These cases were found among a total of 7,090 individuals examined. Urinary bilharzial infection was found in 2,755—that is, 38.9 per cent. Of those infected, 1.7 per cent. had double infection with *S. haematobium* and *S. mansoni*. Among the same series of cases *S. mansoni* infection of the intestinal tract was found in 3,747 out of 7,136 individuals who submitted samples of stools for examination. *S. haematobium* infection of the intestinal tract was found in 65 cases (0.9 per cent.).

It is quite evident from the above that double infection of the urinary and intestinal tract with these two species of bilharzia is by no means rare.

Professor of Parasitology, Faculty of Medicine,  
Cairo, Egypt.

## HEAT CRAMP.

The recent discussion in the *British Medical Journal* on this subject prompts me to write a note on some cases once under my care in which the effects of high atmospheric temperature were manifest in two ways: first, as a mild degree of the heat-stroke common in high temperatures with excessive moisture, well written up in textbooks; and secondly, cases analogous to firemen's cramp, only occurring amongst the engine-room staff of a modern motor vessel, who, though submitted to hard work, do not have the excessive toil of the ordinary ship's fireman. The high engine-room temperature (130° F.) sometimes reached in the tropics is an obvious factor, but associated with it is the rather stagnant air, which is vitiated by exhaust fumes with a high percentage of carbon dioxide.

Without exception the cases occurred in men of the finest physique, the onset occurring after several days' exposure to the conditions with malaise, headache, and crampy pains in the limbs and abdomen. The body temperature was raised to well over 100° F. with rapid pulse. About twenty-four hours off duty, with drugs to relieve pain, and body fluids replaced (tea, lemonade, etc.), served to restore them to normal. I did not try the use of oatmeal water, which is often recommended, but should think this is only an additional way of replacing fluids. As a prophylactic the addition of salt in small amounts to the mess drinking water, as has been suggested by various writers, seemed to prove efficacious, and as no one knew that this was being done there were no complaints about bad water.

Heat cramp in firemen is usually ascribed to excessive tissue fluid and salt loss, which is quite a possible explanation; but in the cases outlined their tasks were nothing approaching the toil of a stokeholder, and suggest some failure of the thermic centre, due to or resulting from insufficient cooling of the body, as by reason of their build the surface weight ratio of the men was diminished, with consequent heat retention, which did not occur in the lighter men doing the same work.

## METASTATIC OPHTHALMIA.

The following case is, I think, worthy of note on account of its rarity and the difficulty in early diagnosis.

A well-developed child, aged 3½ years, had just been discharged from an isolation hospital after treatment for an ordinary attack of measles, from which it had completely recovered; apart from this there was nothing abnormal in the past history. It was brought to the casualty department because the right eye was inflamed; this was considered to be a mild attack of conjunctivitis following measles. When I saw the eye two days later there was considerable injection and chemosis of the bulbar conjunctiva, but the outstanding feature was a very considerable proptosis, with a puffy oedema of both lids. The cornea, anterior chamber, and iris were normal. The case was considered to be one of orbital cellulitis, probably secondary to an ethmoidal infection, but the temperature, and pulse were normal. On admission to hospital an orbital exploration was made, but no pus was found. Three days later a second anaesthetic was given, when the typical yellow reflex of pus in the vitreous was seen through the pupil. The eye was eviscerated and found to be filled with pus, from which a pure culture of pneumococci was obtained. The orbit contained no pus, but showed considerable swelling of all the retro-ocular tissues.

This was a true case of metastatic panophthalmitis; the origin of the pneumococcal infection was probably bronchitis, which so commonly accompanies measles. The septic embolus apparently lodged at the posterior pole of the eye in a retinal or choroidal vessel. This focus of infection must first have made its presence felt in the retro-ocular tissues, hence the very considerable proptosis. The infection took some time to reach the anterior part of the vitreous and so become visible. The correct diagnosis could have been arrived at much earlier had an ophthalmoscopic examination been made, but every indication pointed to an involvement of the orbit; metastatic ophthalmia was not considered.

## BLOOD GROUP PERCENTAGES FOR ARABS, ARMENIANS AND JEWS:

## ANALYSIS OF 1,758 GROUPINGS.

In the course of routine blood grouping of patients at the hospital laboratory during the last five years a certain amount of data has become available which may be of general interest. In the accompanying table the Armenians and Jews represent well-defined unmixed racial groups; under the heading of Arabs a certain number of Turks, Turkomans, and Kurds have been unavoidably included. Their number is relatively small, and the analysis of a small series of "pure" Bedouin Arabs has given practically identical figures for the distinguishing Groups II and IV. It is hoped in the course of the next few years to compile a series for the Kurds, about whom, ethnologically, little is known.

Race.	Number Examined.	Group I.	Group II.	Group III.	Group IV.
Arabs...	933	61=6%	345=37%	194=21%	333=36%
Armenians...	653	42=6%	346=53%	89=14%	176=27%
Jews...	172	14=8%	58=34%	34=20%	66=38%

Note.—It will be observed from the above figures that whereas in the case of Arabs and Jews the relative proportion of Group II and Group IV is as 1 to 1, in the Armenian figures the proportion is as 2 to 1.

## FOREIGN BODY IN THE MAXILLARY ANTRUM.

FOREIGN bodies in the antrum of Highmore are exceedingly rare, and I think the following case is worthy of record.

A girl, aged 7, was admitted to the Victoria Hospital, Bangalore, with the history of having had a swelling of the right cheek for over a year. At first the swelling appeared below the inner canthus of the right eye; an abscess, presumably lacrymal, formed and was incised at another hospital. There was purulent discharge through the incision for about two weeks; it then healed, leaving a minute sinus, but the swelling increased in size and gradually spread to the whole of the right cheek. The right nostril gradually became blocked, and for six months the patient

had not been able to breathe through it. Occasionally there was bleeding from the nose.

On admission to the Victoria Hospital the whole infra-orbital region on the right side was found to be swollen and slightly oedematous; the furrow between the nose and the cheek was obliterated. There was a small lacrymal fistula, which discharged a drop of pus on pressure. The right eyeball was pushed slightly upwards and the right nostril was almost completely obliterated, speculum examination being impossible. The right side of the palate was pushed downwards. There was no pain or tenderness over the cheek or palate. Transillumination showed marked opacity on the right side.

A Caldwell-Luc operation was performed. On making the usual incision through the gingivo-labial fold and retracting the labial flap upwards the anterior wall of the maxillary antrum was found to be absent, and a finger was easily introduced into the antrum. A large mass of cholesteatoma, of the consistency of putty, was evacuated, and in the middle of it a hard oval rhinolith was discovered. A large opening in the lateral wall of the nostril was present, establishing a communication with the antrum. Adhesions in the nostril were carefully broken down. After thoroughly clearing the antrum it was treated with bipp, lightly packed with gauze, and drained through the nose, the gingivo-labial incision being finally sutured. On breaking the rhinolith it was found to consist of a whole tamarind seed, with a thin crust of calcareous deposit on it.

The gauze plug was removed after forty-eight hours, and the antrum was irrigated daily through the nose. The patient made an uneventful recovery and was discharged cured two weeks after the operation.

In the *Revue de Laryngologie, d'Otologie et de Rhinologie*, 1924 (vol. xlv, p. 406), Gamalein reported a similar case in which maxillary sinusitis was kept up for two years by a shell splinter which had entered the antrum through the cheek. I am indebted to Mr. H. E. Powell, librarian of the Royal Society of Medicine, for this reference.

In the case here recorded the following features are worthy of note:

1. The foreign body evidently entered the antrum from the nares after ulcerating through its lateral wall.
2. Infection spread into the lacrymal sac through the nasal duct, and when the primary focus of suppuration was removed the lacrymal fistula healed.
3. The foreign body remained in the antrum for an unusually long time; I think it must have been there for at least four or five years, since the patient had no recollection of having introduced the tamarind seed into the nose. Evidently it must have been put in when she was only 2 or 3 years old; the subsequent deposition of calcareous matter had converted it into a rhinolith.

## Reports of Societies.

### TREATMENT OF CANCER OF THE CERVIX.

At the meeting of the Medical Society of London on March 26th, with Mr. H. W. CARSON, the president, in the chair, two papers were read—ono by Dr. H. R. SPENCER on advances in the treatment of cancer of the cervix, and the other by Dr. MAX CHEVAL of Brussels on treatment of cancer of the cervix by radiation. The papers are printed at pages 535 and 537.

In the discussion that followed Dr. J. F. McCANN declared his scepticism with regard to cancer statistics, a scepticism which had not diminished after watching the work of different surgeons at home and abroad. He questioned the common idea that cancer was a local disease; his own impression was that it was a general disease of obscure origin, with local manifestations. If one happened to know the patient before the cancer developed he thought it would be found that in the majority of cases there was a period of subhealth before any cancer manifestation appeared. He referred to the striking differences in the results of treatment in cases which superficially were similar, and he traced the reason for the difference to some factor, as yet not understood, in the patient herself. Was cancer ever cured? What puzzled him was not the frequent recurrences, but that it should happen that patients went for as long as twenty years or more after operation without recurrence. At the same time one felt

that if such patients lived long enough the cancer would at some time or other recur. As to favourable signs in prognosis, he thought the most important was that the patient gained in weight after the operation. The type of patient was also an important matter. He himself viewed with much more misgiving the stout woman who came up for operation than the elderly dried-up woman, upon whom probably the results of operation, whether limited or extensive, would be much more successful. He was not yet convinced that better results could be obtained with radium than with the knife, though if such were proved he would give up the knife at once.

Dr. MALCOLM DONALDSON discussed the advantages and disadvantages of operation in cases of carcinoma. One of the disadvantages was that the operating technique took years to learn, and that the initial mortality among patients undergoing operation was considerable; further, the fear of operation deferred many patients from seeking advice sufficiently early. On the other hand, there were certain points in favour of radiotherapeutic methods: the initial mortality was negligible, and the technique was so simple that any gynaecologist could employ it after experience of a few cases. The disadvantage of radium therapy was that at present there was no scientific evidence that one could deal in that way with infected glands. It might be said that there were two schools, each practising a different technique; one of them believed in putting radium on the cervix, and another in putting it into and around the growth by means of needles. It was in Brussels that he first saw the needle technique, and he had been impressed by it ever since. But it was necessary in all these cases to wait for a number of years before speaking with any assurance of the real character of the results. A certain amount of investigation on what was happening in the individual cell under the action of the radium had been carried out at Cambridge in the Strangeways laboratory. The evidence so far obtained, working with tissue cultures, was that more damage might be done by small doses employed over a long time than by large doses employed for a short time. It was well known that the gamma rays of radium had a selective action on all quickly growing tissues. He proceeded to show on the screen tables of cases, operable and inoperable, treated at St. Bartholomew's, with the mode of treatment and the duration of the result. A combination of Wertheim's operation with radium had given good results in some cases.

Dr. DOUGLAS WEBSTER thought it desirable that massive radium therapy, the radium being used at a distance, should be considered, and it appeared rather extraordinary to him that the head of the Radium Institute, in a recent address before another society (*British Medical Journal*, March 24th, p. 496), should have stated that he did not believe specially in distance radium therapy. The speaker thought that results obtained elsewhere suggested that this was a very valuable method. With regard to x-ray work, one interesting point in connexion with gynaecological treatment was the use of deep x rays, both pre-operative and post-operative, in combination with surgical work. He thought there was considerable value in a combination of methods.

Dr. SIDNEY FORSDIKE said that nowadays one rarely opened a medical journal without finding a report of a number of cases of carcinoma relieved by radium, but what it was necessary to reach was a greater degree of certitude with regard to cure. He himself treated six operable cases in this way in 1921-22, and out of the six, four were still alive and well. When dealing with early carcinoma of the cervix by radium, it was his experience that in one-third of the cases the glands were affected, and he was perfectly sure that the application of radium in the vagina and uterus would not influence the infected glands in the ileum region. He was a little doubtful about Dr. Donaldson's remark that anyone could learn radium technique very quickly; in a certain clinic he found an eminent gynaecologist using radium evidently with insufficient knowledge of the agent he was employing. The important thing about radium was the dose, and the dose was determined not only by the number of hours the radium was left in position, multiplied by the weight of the substance, but also by the nature and thickness of

the screen employed and the distance of the radium from the growth.

In further discussion Dr. G. VILVANDRE spoke of the limitations of x rays in treatment, especially in deep therapy. If only an x-ray tube, actuated from a source of superlatively high voltage, could be made, results more striking and consistent might be forthcoming. Dr. BARNARD referred to the frequency with which in carcinoma of the cervix extraordinarily rapid and widespread dissemination was seen. Dr. A. GOODWIN mentioned the value of radium following upon operation, but recounted particulars of one or two accidents with radium, such as lost needles. Dr. SPENCER confined his reply to praise of Dr. Cheval's contribution to the subject, and Dr. CHEVAL added a few words, in which he argued against the too abundant use of needles, and also urged great care as to the dose actually given, especially in relation to the distance from the source of radiation to the tumour.

### THE PULPLESS TOOTH.

THE Sections of Odontology, Electro-Therapeutics, and Pathology held a combined meeting at the Royal Society of Medicine on March 26th for a discussion on the pulpless tooth. Mr. W. RUSSTON was in the chair.

Mr. FRANK COLEMAN, in a general introduction to the subject, said that more than half the population had pulpless teeth in some form or other, and in 10 per cent. the number of pulpless teeth might be from five upwards. He assumed the term "pulpless tooth" to denote a tooth from which the pulp had been removed, and the tooth subsequently treated by filling, crowning, or some other means. A pulpless tooth should not be designated a "dead" tooth, for the periphery of the tooth, the cementum, retained some vitality through its periodontal membrane. The main principles concerned in the treatment of teeth with exposed live pulps or teeth containing dead pulps were the following: (1) To remove as far as possible every trace of pulp tissue. In teeth with live pulps the desensitization of the pulp must first be assured. This could be brought about by the employment of a local anaesthetic or a caustic (usually arsenic), in which latter case a few days must elapse to bring about complete devitalization. The method by local anaesthesia was more scientific and would leave the tooth in a less unhealthy condition. (2) To cleanse the root canal or canals of the teeth, and to treat the periapical tissues via these channels. (3) To fill the cavity of the teeth when the periapical tissues had ceased to discharge through the canal and had formed a scar at the tooth apex. Most dental surgeons recommended filling the roots of the teeth as well as the cavity in the crown (that is, the pulp chamber), as by this means the periapical tissues could be further treated if and when necessary. The method of treating pulpless teeth which he himself had followed for nearly a quarter of a century depended upon the supposition that a scar formed around the apex of the tooth soon after the removal of the pulp. The operation of excising the end of a tooth involved in periapical destruction did not appeal to him as a rational method of treatment. The extent of disease of the root was incapable of diagnosis, as no line of demarcation was formed between the living and dead portions of the teeth. It therefore became merely the empirical removal of a certain amount of necrotic root. The opening and scraping of sinuses connected with dead teeth, the injection of drugs through those sinuses, and other such-like methods were only palliative whilst the cause remained.

Mr. OWEN C. MORPHY said that all dental surgeons were conscious of the gaps in their knowledge of this problem. He himself was inclined to the removal of pulpless teeth as far as possible, but there were many occasions when an attempt to save even a definite septic tooth was desirable and justifiable. The fundamental principles underlying such an attempt were that the patient must be in good health and, except in rare instances, not beyond middle age. The justification for the saving of such a tooth was that it obviated partial denture, which might sometimes lead to a greater degree of infection than arose from one or two pulpless teeth. He mentioned that that well-known

observer Weston Price, who, with a team of dental surgeons, bacteriologists, and laboratory workers, had carried out a very extensive investigation in dental sepsis, had produced a mass of evidence condemning the pulpless tooth, but his experiments were conducted on rabbits, which were very susceptible to streptococcal infection, and, moreover, received a sudden massive dose, giving them little chance of developing immunity, which was not the way in which infection ordinarily developed. The speaker believed in the value of zinc and iodine ionization for sterilizing those portions of the root not accessible to mechanical measures, the galvanic current conveying the ion into and through the finest channels.

Dr. H. M. WORTH spoke from the radiographic point of view. He said that there were no intrinsic radiographic changes to be seen in a tooth without a pulp, but there were often certain appearances in or around such a tooth which were of great value in aiding its recognition. After discussing, with the aid of radiographs, the evidence which might be regarded as certain that a tooth was pulpless, and the evidence that was only suggestive, Dr. Worth said that the radiograph was of use at the commencement of treatment to eliminate the presence of apical infection, and later to follow the effect of treatment on apical osteitis. It was important to know whether the apex of a tooth under treatment was completed. A tooth with a completed apex showed the pulp canal converging towards the apex, whereas when the apex had yet to form the canal was seen to diverge towards the apex and the apical foramen to be "funnel-shaped." To ascertain the number, direction, and length of the root canals it was advisable to insert small metallic broaches before taking a radiograph. During the process of treatment of root canals it was sometimes necessary to ascertain the presence of pulp nodules in the canal, or of a piece of broken instrument. Perforation of the apex or side of a tooth was usually seen only in a radiograph when a metallic broach or piece of wire had been inserted into it before radiography. It was often considered necessary in the treatment of a root canal that the apex should be reached by the filling material, and consequently a radiogram was indicated to ascertain this point. Occasionally the filling would be seen to have passed beyond the apex. He indicated the limitations of x-ray examination, and pointed out that radiography was only a "positive" test of the vitality of a tooth.

Dr. G. MURRAY LEVICK spoke on the value of light in the treatment of septic infection. The use of artificial light was the subject of a good deal of misconception. The destruction of micro-organisms was a side issue. The clearing up of septic infection in various parts of the body following a well-directed application of general light treatment was an indirect effect due to the conversion of the rays into an indirect energy in the tissues, so that the substances were chemical energy and distributed throughout the body. It was synthesized and distributed throughout the body. It was absurd to attempt the destruction of bacteria in infected gums and teeth by ultra-violet rays, whose lethal effect was so very superficial. He strongly deprecated the application of ultra-violet radiation to mucous membrane; it was dangerous and unjustifiable, and some very unfortunate results had been seen following such applications to the throat. He urged the value of local treatment by the red rays, under whose action various infective conditions cleared up. In the direct treatment of pyorrhoea red rays were of proved value. Gums which were spongy and bled easily and gave some purulent discharge were found to clear up under this particular form of radiation, which, however, should be supported by general irradiation of the body by ultra-violet and light rays.

Mr. A. T. PITTS said that he was scarcely optimistic enough to think that any great amount of light was going to be shed on a particularly dark problem as a result of that discussion. He wished to say a word about pulpless teeth. The only place for them, in his view, was the dustbin. Treatment for pulpless deciduous teeth was not really legitimate. With regard to the permanent teeth, there must be a discrimination between teeth devitalized by the dental surgeon and teeth already dead. He believed it to be permissible to treat dead teeth, but a much greater responsibility was now laid upon the dentist in this respect than was the case twenty years ago. His treatment must

be in the main antiseptic rather than aseptic, for aseptic dentistry, he thought, was not yet practicable. In the details of treatment he himself preferred to fill canals rather than leave them open as Mr. Coleman had suggested.

Dr. F. J. BRALLSFORD discussed, with the help of many radiograms, the x-ray appearances of pulpless teeth, and gave an analysis of radiographic pitfalls, which, he said, might arise from faulty technique or from misinterpretation. Misinterpretation of the radiograph was due largely to lack of experience in studying shadows and to lack of knowledge of general and dental pathology. Every radiologist who had correlated the radiographic and clinical, operative, and post-mortem findings knew that the radiograph might show only slight changes, even when a massive lesion was present. Thus, with acute inflammatory lesions of the skeletal tissues the radiograph might give no sign. One could almost say, especially in acute conditions, that the more attractive the physical signs the less the radiographic signs. In the case of dental radiography, as the lesions were often small, it was all the more important to pay attention to the finer details. There was no question that for the best interpretation of radiographs the observer must have a good knowledge of the normal and pathological anatomy of the part.

Dr. MEYRICK JONES recalled that pathological changes seen in radiograms were not produced immediately, but were the result of a long morbid process. Recent infections, even though severe, often showed no signs radiologically. There should be complete co-ordination between the work of the dental surgeon and the physician. He quoted some authorities to the effect that whenever a tooth showed pathological change it should be extracted. The speaker himself believed that a pulpless tooth in a patient who was the subject of general sepsis should be extracted, even if it showed no pathological change; in such a case the tooth might at any time become a secondary focus. In the healthy, vigorous young adult, if a pulpless tooth were left *in situ*, it should be periodically reported on after radiological examination.

Dr. A. LIVINGSTON joined issue with Dr. Worth, whose contention that the vitality or the pulplessness of a tooth could be diagnosed by radiological examination appeared to him unconvincing. Any contention based on the presence or absence of the lamina dura fell to the ground, because the lamina was not continuous. A cyst half an inch in diameter might show involvement of adjacent teeth, and although those teeth were stripped of their periodontal membrane yet they were alive. He did not agree with Dr. Coleman with regard to unfilled canals. The speaker did not think this method entirely satisfactory, for, in the event of accident to a tooth so treated, it could not be expected to resist infection—certainly not caries. He showed his own method of filling by silver nitrate. With regard to apicectomy, this was a successful operation, but it must be premised that cases subjected to it were carefully chosen and the best possible technique applied. It was never certain what was behind the apex of a tooth, and it was always possible that there might be organisms present.

Mr. ST. J. STREADMAN did not agree with Mr. Coleman that apicectomy was an empirical method of removing a portion of the root which was dead; his own special object was to deal effectively with the last quarter of an inch, which was the important part. In apicectomy he employed a big incision with a large flap. He showed lantern slides of the teeth of a girl aged 19 on whom he had successfully employed the operation.

Mr. NORMAN GRELLER held that a pulpless tooth should not be retained. Inflammation might exist at the apex of a pulpless tooth without producing symptoms, and it was very likely that radiography would give no evidence at all. As a dental surgeon and as a radiologist he had come to the conclusion that many pulpless teeth became sooner or later the seats of infection, and the majority of pulpless teeth were those from which a live pulp had been removed in the process of filling. In dealing with these matters it should always be borne in mind that there was possibility of infection of the jaw.

Dr. A. C. JORDAN had considerable sympathy with the dental surgeon who tried to save a dead tooth, but he

thought the effort foredoomed to failure. He believed that radiologists should confine their attention to obtaining a good radiograph and reporting what it appeared to show; they should not attempt to prescribe. He hoped that dental surgeons would impress upon patients the importance of a proper diet.

Dr. G. B. BATTEN agreed that the majority of pulpless teeth sooner or later caused trouble, but he cited himself as an exception, since he had a pulpless tooth which had given him no difficulty for twenty years.

The CHAIRMAN (Mr. Rushton), summing up the discussion, mentioned that thirty years previously he had plugged a tooth of one of his pupils with cotton-wool soaked in iodoform, and it had only recently been extracted. He did not suggest that that was the system he practised to-day, but the case illustrated the length of time for which a pulpless tooth might last. He himself had a pulpless tooth which he did not think came into the category of a pathological entity as insisted on by some of the speakers. He believed that if a person was healthy, with a vigorous resistance, little harm would come from a filled tooth.

### TREATMENT OF URETHRAL STRICTURE BY EXCISION.

At a meeting of the Section of Urology of the Royal Society of Medicine on March 22nd, with the president, Mr. FRANK KIDD, in the chair, a discussion took place on the treatment of urethral stricture by excision.

Mr. Frank Kidd opened with a brief survey of the history of the operation, followed by a short description and comparison of the methods of Hamilton Russell and MacGowan. It was claimed by these surgeons that complete excision of a portion of the urethra did not interfere with the blood supply or the power of erection, and that there was no recurrence of the stricture requiring further passage of bougies. Mr. Kidd favoured MacGowan's procedure with preliminary suprapubic cystotomy and the passage of retrograde bougies from the bladder to the stricture, since isolation of the posterior urethra and the division of the compressor urethrae produced incontinence. He said that the use of the operation of excision of urethral stricture was very limited, since most strictures could be treated and cured by internal urethrotomy with subsequent use of Kollmann's dilator or by simple dilatation. He had employed excision chiefly in periurethral infection with fistula formation, and in cases of hard, palpable tunnel stricture. He stated that for a successful result the free excision of septic wounds, tracks, and fibrous tissue was essential. He had found that excision of fistulae was a much more satisfactory procedure than wide drainage. Since almost all strictures were situated in front of the triangular ligament there was no need to damage the posterior urethral muscles, and if he found a fistulous track passing through the compressor urethrae muscle he did not damage this structure by following the track through it, but merely ligatured the track on the surface of the muscle, since the deeper portion of the fistula usually disappeared. If possible he tried to leave the roof of the urethra, but if this was not advisable he excised the affected portion completely, mobilizing the anterior portion in order to join the cut ends, but never mobilizing the posterior portion, owing to the risk of incontinence. He repaired the urethra over a metal bougie, which was removed at the end of the operation, and suprapubic drainage was continued for about fourteen days until the perineal wound had healed. He did not know whether excision obviated the necessity for less frequent post-operative dilatation than other methods, because most of the patients on whom he practised excision had been sailors with neglected strictures, who did not attend for further observation after operation. Mr. Kidd concluded by saying that excision should be employed more often in preference to external urethrotomy, always in cases complicated with fistulae, and in some inflammatory and traumatic tunnel strictures and strictures of the penile urethra. He mentioned the value of thyroid extract as a means of rendering strictures more easily dilatable.

Mr. E. T. C. MILLIGAN said he used the same technique as Mr. Kidd. He remarked that Hamilton Russell had now given up the deep dissection of the posterior urethra, and did not open the membranous urethra. Mr. Milligan described the urethroscopic appearances in the development of a stricture, and also the effect of various methods of treatment, as seen through the urethroscope at various periods after treatment. He showed some excellent pictures to demonstrate his observations. He pointed out that in inflammatory strictures the condition commenced in parallel rows of follicles in the roof of the anterior urethra, spreading gradually to the sides, and rarely to the floor. He divided strictures into two main types: (1) where the centre of the stricture was avascular, translucent, and confined to the mucous membrane, and (2) strictures composed of vascular, opaque, fibrous tissue, with spread of fibrosis into the corpus spongiosum. He added that gonorrhoeal strictures should never be allowed to pass beyond type 1. For the treatment of type 1 dilatation was usually sufficient, but, as he had noticed on urethroscopic examination, within one week the stricture and fibrous tissue had reformed. He mentioned that the urethra was normally a closed tube, only dilated to a small degree by the passage of urine, the urethra being, therefore, in a position of rest for most of the day and usually all night. To overcome this he always tied in a catheter for one week after dilatation or operation to keep the urethra dilated. Most strictures were of this type.

The second type presented the problem in treatment. Mr. Milligan first tried simple dilatation, and observed the effect with the urethroscope. If this method was not satisfactory he performed internal urethrotomy and tied in a catheter to prevent collapse of the urethra. This was a very satisfactory operation, since the cut was in the roof of the urethra. He did not think that excision was likely to overshadow internal urethrotomy. The speaker said he had performed excision in cases of stricture uncontrolled by dilatation and internal urethrotomy, as demonstrated by frequent urethroscopic examinations, and in all cases of stricture complicated by fistula. After excision of a stricture he had found that the urethra was kept permanently open by periurethral adhesions. He had observed recurrences of strictures about four years after operation, coincident with the disappearance of the adhesions and mobilization of the urethra. It was very important to excise freely and widely all fibrous tissue to ensure success. Excision was far superior to external urethrotomy, since in this latter operation the roof of the urethra was untouched.

Mr. OGER WARD stated that he freely dislodged the corpus spongiosum from its bed in front of the stricture, and then, if possible, behind the stricture. If he could not do the latter he never opened the bladder behind the stricture, but stripped the urethra from before backwards, looking for the dilated urethra behind the stricture. There was little danger in doing this, as the dilated urethra was usually immediately opened up before the dissection had passed very far posteriorly. He did not perform suprapubic cystotomy except in cases of urethral fistulae. He pointed out the difficulty and importance of preventing the perineal catheter passed into the bladder from touching the suture line. Extension of the stricture into the membranous urethra was found at operation in one case, and he had to dilate this with metal dilators before repairing the channel. In his opinion, excision of an impassable stricture was far superior to external urethrotomy. He had found that in some of his cases after excision dilatation was not always easy. He was doubtful, therefore, whether there was less need for post-operative dilatation with this operation than with other operations, and also whether excision was a cure for stricture as had been claimed.

Mr. FOWLER WARD said that he never cut the bulbocavernosus muscle, but reflected it. He considered internal urethrotomy a blind operation, and emphasized the risk of severe haemorrhage. For an impassable stricture he performed suprapubic cystotomy, passed a retrograde bougie, divided the stricture in the perineum, and introduced a metal catheter through the urethra into the bladder, leaving it in for seven days. If this could not be done, owing to a great deal of fibrous tissue, he then excised

the stricture. He reported several cases of stricture of the penile urethra in which he had used plastic skin flaps, restoring the urethra with complete success. He emphasized the importance of always employing drainage of the bladder, either suprapubic or perineal, in all cases of plastic operations on the urethra.

Mr. KENNETH WALKER reported that he had found excision of great help in traumatic strictures. He commented on the difficulties at operation when the stricture was far back in the anterior urethra, and remarked that though he was often dissatisfied with the immediate appearance of his repair of the urethra, he found that the end-result was very satisfactory.

Mr. CLIFFORD MONSON mentioned the marked improvement in recent years in the treatment of gonorrhoea, and the early and preventive treatment of urethral stricture. He believed that in the future operations would only be necessary in traumatic strictures. Internal urethrotomy was at the present time a comparatively rare operation.

Mr. WINSBURY WHITE said that some of the worst strictures he had to treat were those following external urethrotomy. In almost all cases of stricture a filiform bougie could be passed after patient manipulation, and then internal urethrotomy could be performed.

Mr. KIDD, in reply, said that internal urethrotomy was good and most useful in the majority of strictures, but excision was necessary in some advanced cases and cases with urinary fistulae. The use of a small knife in the urethrotomy obviated the risk of severe haemorrhage after internal urethrotomy.

#### PATHOLOGY OF THE MAMMARY CONNECTIVE TISSUES.

At a meeting of the Manchester Pathological Society on March 14th, the president, Mr. F. H. WESTMACOTT, in the chair, an address was given by Sir G. LENTHAL CHEATLE on normal and abnormal states of the connective tissues in the breast, illustrated by specimens and lantern slides.

Sir Lenthal Cheatle said that the general supporting tissue of the breast, like fibrous tissue elsewhere, was liable to sarcoma and fibroma, but these were not true breast changes. A sarcoma could only be diagnosed from a fibroadenoma by studying a whole section of the breast. It was impossible to separate hyperplasias of the true breast connective tissue from the accompanying epithelial hyperplasias; the pathological importance of the combination was seen in the papillomata. Physiological influences had a great bearing on the generalized (and as a corollary on the localized) hyperplasias. In a section shown of the breast of a woman, aged 42, which very closely resembled a state of "chronic mastitis," two points were striking: first the presence of fibro-adenomata, formed and forming; and secondly, the hyperplasia of the pericanalicular and periacinous connective tissue. A consideration of the normal breast at puberty and at birth would show physiological relations between the formation of fibro-adenomata at puberty on the one hand and the so-called "chronic mastitis" on the other. Both of these conditions were manifest in the specimen described. In the normal breast at puberty there was an enormous increase of acini and a hypoplasia of the pericanalicular and periacinous tissue, among which lymphocytes were common. The fibro-adenomata which were so common at puberty consisted of hyperplasia of the pericanalicular and periacinous tissues, and, in some of them, new acini developed, so that in the pathological part of the breast there was only an irregularity of the physiological activity which was progressing in the rest of the same breast. Lobulation of fibro-adenomata was not due to outgrowths from the original tumour, but to primary similar and later changes in the breast tissue adjacent to it. The presence of lymphocytes among the hyperplastic pericanalicular and periacinous tissues in the normal breast at puberty gave all the morphological characteristics of so-called "chronic mastitis," and was thus evidence that this term was an incorrect nomenclature. At birth it was impossible to distinguish a male from a female breast; in both a desquamative epithelial hyperplasia, filling the ducts, together

with a hyperplasia of the pericanalicular and periacinous connective tissue, containing lymphocytes, gave an appearance which, in the adult, would certainly be diagnosed as "chronic mastitis." This condition in the adult was not an inflammation, but a physiological change become pathological by reason of its irregularity and of its exceeding the normal. In passing, it was pointed out that most breasts of the age to which this condition belonged only appeared nodular on the surface owing to hypertrophy of the ligamenta suspensoria of Cooper, which isolated fat nodules. If the skin was undercut, the nodularity disappeared. Such breasts were never adherent to the pectoral fascia, as might be the case in the rare nodular breasts which were the seat of carcinoma. The elastica was next considered. Hyperplasia might be (1) general and associated with carcinoma or with dysgenetic epithelial hyperplasia, or (2) local, in conjunction with carcinoma, epithelial hyperplasia, Paget's disease of the nipple, or hyperplasia of the intra-elastica. It did not represent a local resistance to the malignant invasion. Finally, hyperplasia of the intra-elastica was described; in this state it often underwent early degeneration. Hyperplasia of this tissue did not affect the whole breast, and it might not produce a localized tumour. On the other hand, it might form one kind of intracanalicular fibro-adenoma (which the lecturer believed to be common), and also certain uncommon, unbranching papillomata.

### COLLOIDAL LEAD.

At a joint meeting of the Manchester Medical Society and the Liverpool Medical Institution at Manchester on March 7th, Professor W. J. DILLING of Liverpool read a paper on colloidal lead.

Professor Dilling said that the standards on which the suitability of various colloidal lead preparations for use in the lead treatment in carcinoma had been approved had been (1) that intravenous injections representing 0.025 to 0.05 gram of lead per kilo body weight should be tolerated by rabbits without local irritation, immediate or late symptoms, and (2) that similar injections in cats should cause neither respiratory nor circulatory disturbance. The latter was the greater safeguard, since a decided, although brief, fall in blood pressure, synchronous with, and due to, impairment of the contractility of the auricular muscle, resulted from injections of ionized lead solutions and many colloidal lead preparations. Tracings from cats showed this effect on the auricle, with consequent diminution of the pulse wave and of blood pressure; large doses of "approved" lead colloids frequently repeated could produce similar effects. Microscopical examination of the tissues of mammals injected with lead colloids revealed fine granules, which microchemical tests indicated were colloidal lead; a series of microphotographs showed these free in the blood vessels and in the interior of leucocytes. The spleen contained large numbers in the splenic pulp, free in the blood sinuses, forming extranuclear rings in the splenic cells, and concentrated in the phagocytic splenocytes; the Malpighian corpuscles contained relatively few particles or none, and where they occurred they were merely minute. The liver contained particles, but their distribution varied; they occurred in the blood sinuses, in the hepatic cells, and in the endothelial cells of Kupffer. In the kidney, particles had been found within the glomeruli and punctuating the outlines of the convoluted tubules. This organ almost invariably showed evidence of degeneration of the secreting cells of the cortical tubules, loss of nuclear staining, and occasionally necrosis; glomerular congestion and haemorrhage had also been observed. Particles were also present in the lung, but owing to the presence of carbon granules their exact distribution was uncertain. Granules had not been found in any other tissue with certainty. Microphotographs of the spleen and the liver of a case of lead acetate poisoning in a man also exhibited granules in comparable positions. Chemical analysis of mammalian tissues from these experiments with the chromate method confirmed that the lead was in highest concentration in the spleen, liver, lung, and kidney, and in the blood. The percentage in other tissues examined, including bone, was relatively low, but

indicated the commencement of excretion by the bile and urine. The lead granules were apparently concentrated chiefly in the reticulo-endothelial system, but it had not yet been possible to trace them to the endothelial cells of the lymph glands, of bone marrow, or of connective tissue. The only organ in which histological damage was apparent after large colloidal lead injections in animals was the kidney. The clinical importance of this fact was emphasized.

### Gastric and Duodenal Ulcers.

Mr. F. STRONG HEANEY (Liverpool) reported a series of 183 consecutive gastric and duodenal ulcers operated on by him during the past four years. He had, with the assistance of Dr. Aidin, followed up and obtained the end-results after a year in about 90 per cent.; the cases included 33 perforations, 65 chronic duodenal ulcers, and 85 gastric ulcers. Among the 33 perforations, the early mortality was 8.7 per cent., and the follow-up showed good end-results in 90 per cent. of the remainder. In 31 cases, in addition to repair and pelvic drainage, gastro-enterostomy was performed. There were two unsatisfactory end-results: one case where gastro-enterostomy had not been performed, and one where the gastro-enterostomy opening contracted; both required a further operation. In chronic duodenal ulcer the operation consisted of a vertical gastro-enterostomy running into the lowest point of the great curvature, in some cases with infolding of the ulcer, and in some with appendectomy. The mortality in hospital was 3 per cent., almost entirely from post-operative pulmonary complications. The "follow-up" showed good end-results in 90 per cent. of those leaving hospital alive. There were two gastro-jejunal ulcers (3.1 per cent.), one arising four months and one four years after gastro-enterostomy; both were cured by partial gastrectomy. The other unsatisfactory end-results happened in patients who for one reason or another did not have appendectomy performed at the same time as gastro-enterostomy. Present symptoms in almost all were suggestive of recurring appendix trouble. This, however, may have been a coincidence, as the end-results after gastro-enterostomy for perforation showed no such symptoms, although in all the latter the appendix had been left undisturbed. Chronic gastric ulcers varied so much in clinical picture and operation findings that for the purpose of useful comparison they were subdivided into complicated and uncomplicated. The uncomplicated included small or moderate-sized ulcers situated at the pylorus or near the lower part of the lesser curvature without serious adhesions. The complicated included the larger ulcers of the posterior wall, those with perforation of neighbouring structures, those situated high in the stomach, and those accompanied by cholecystitis, ptosis, and hour-glass contraction. Of the 55 uncomplicated cases gastro-enterostomy was performed in 54, with 2 deaths, both from pulmonary complications. In the remainder the end-results were uniformly satisfactory. Mr. Heaney briefly referred to the present views on the etiology of gastric and duodenal ulcer in the light of the experimental work of Morton, and to the relation of chronic gastric ulcer to gastric cancer. In his series there was no instance of cancer being found in the "follow-up" in any case of simple gastro-enterostomy for gastric ulcer, nor was there any instance of cancer arising after excision or gastrectomy where the specimen removed at operation was reported histologically non-malignant.

### CHOCOLATE CYST OF THE OVARY.

At a meeting of the Midland Obstetrical and Gynaecological Society, held in Birmingham on February 14th, with Professor D. C. RAYNER, the president, in the chair, Mr. ALFRED DANBY exhibited a specimen of a large chocolate cyst of the ovary, which he had removed from an unmarried woman, aged 26.

Mr. Danby said that the history was interesting, since apart from rather severe pain on the first day of her period, the patient had always been healthy. The cyst had been discovered during a routine medical examination. There was a symmetrical mid-line hypogastric swelling reaching to the umbilicus, the size being that of a twenty

weeks pregnancy. It could not be distinguished from the uterus, and an x-ray examination was made to exclude pregnancy. On opening the abdomen a brownish-purple tumour was found arising from the pelvis, and reaching as high as the umbilicus. It was densely adherent to the surrounding structures, more especially to the posterior wall of uterus and rectum, the right adnexa, the appendix, and the great omentum. An ovarian trocar was inserted, and nearly two pints of thick chocolate-coloured fluid removed, containing many blood cells, but no oxy-haemoglobin. An analysis showed 30 mg. of urea, 14.15 mg. of calcium, and 354 mg. of cholesterol in 100 c.cm. No sugar was found. The tumour was removed with difficulty owing to dense adhesions, and several parts of the wall had to be sacrificed. Large bare areas in the pelvis were exposed; these were peritonized as much as possible, and owing to a considerable amount of oozing a rubber drain and gauze packing were inserted. Convalescence was uneventful. Histological examination of the wall of the tumour failed to disclose any endometrial remnants. Some of the sections consisted of ovarian stroma, and in others the structure was that of dense fibrous tissue with red blood cells scattered about in it. Mr. Danby said that the specimen he was showing had unfortunately shrunk considerably since it was removed. He had no doubt that it conformed to Bailey's stage VI in the life history of the endometrial type of tumour of the ovary, but it appeared to be larger than any that writer had described in his paper. A considerable part of the wall of the tumour was composed of thinned-out and compressed ovarian stroma, suggesting that the ovary had been extensively excavated and stretched out on its surface. The failure to demonstrate the presence of endometrial tissue from the cavity of the larger of these tumours was not unusual. To meet with any measure of success it was necessary to cut serial sections, but this was not done in this instance.

#### *Dystocia due to Hydatid Cyst.*

Mr. MASLEN JONES (Wolverhampton) communicated the notes on a case of Caesarean section for hydatid cyst obstructing labour. A primipara, aged 25, had been operated on four years previously for "cysts on the liver." Twelve hours after the commencement of labour the midwife had called in a doctor, who found a cystic swelling in the pouch of Douglas. When the patient was seen by Mr. Jones an hour later dilatation was complete, but the advance of a normal vertex presentation was prevented by this cystic swelling, which could not be displaced. Obstruction due to hydatid cysts was diagnosed, and Caesarean section was successfully performed. During the operation the pelvis was examined and was found to contain some isolated intraperitoneal cysts, an extraperitoneal cyst in the left half of the pelvis, and a cyst in the left ovary. Convalescence was uneventful, and the patient refused any further operative treatment. Because of general malaise and a pain in the chest she came up to the out-patient department in February, 1928, when a flaccid cystic mass filling the pelvis and reaching nearly to the umbilicus was found. An x-ray examination of the chest was negative. An operation was performed, and the specimens produced at the meeting included four cysts, which were lying on the raised floor of the pouch and loosely attached to the peritoneum and omentum. One of these had invaded the mesentery of the appendix, which had been removed with the cyst. A large specimen consisted of the uterus and both appendages; there was a cyst the size of a golf ball growing from the right ovary, and a very large cyst, which was partially intraligamentary, crossed the mid-line in the floor of the pouch, and had completely replaced the left ovary. Macroscopically the isolated cysts were typical hydatids, whilst the others appeared to be ovarian in origin. Mr. Jones said that full pathological findings would be reported later.

#### *Sarcoma Botryoides.*

Mr. MASLEN JONES also read notes on a case of sarcoma botryoides occurring in a girl, aged 18, who had complained of continuous haemorrhage for eight weeks. A fleshy polypoid mass protruding through the vulva was found to have an annular base of attachment round the cervical

margin, being practically a tubular prolongation of the cervical mucosa. The growth was removed by a circular amputation of the cervix. Histologically it was a mucous polypus showing no evidence of malignancy. The patient was not seen again until five months later, when she complained of continuous haemorrhage for three weeks, and a large mass of numerous semi-translucent polypoid bodies was discovered distending the vagina. It was evident that the condition was sarcoma botryoides. Histologically the grape-like bodies were found to consist of myxomatous tissue containing stellate and round cells, with a covering of squamous epithelium. The stellate cells were the more numerous, and were identical with those found in a myxoma or myosarcoma. More on clinical than histological grounds panhysterectomy of the Wertheim type, including the greater part of the vagina, was performed. At first the patient progressed well after the operation, but six months afterwards there was evidence of a recurrence in the abdomen which was considered inoperable. She died a month later with signs of pulmonary metastases during the last weeks of life. Leave for a necropsy was refused.

#### *Pulmonary Embolism following Delivery.*

Mr. FURNEAUX JORDAN showed a specimen of pulmonary embolism from a primipara, aged 45, who had had a natural delivery followed by a normal and apyrexial puerperium. She was allowed to get up on the eighth day, when, on walking to a chair, she suddenly became giddy. She was at once put back to bed, but later became cyanosed, dyspnoic, and retched frequently. Later there was very severe epigastric pain and restlessness; she rapidly became unconscious and died two and a quarter hours after the first symptoms. At the necropsy a firm embolus 2½ inches long was found at the bifurcation of the pulmonary artery. The uterus was well involuted and the placental site was normal. There was a small degenerating fibroid in the anterior wall of the uterus.

#### *Hydatidiform Mole.*

Mr. FURNEAUX JORDAN showed also a specimen and microscopic slides of a case of chorion-epithelioma occurring in a primipara, aged 28, who nine months previously had had a hydatidiform mole removed.

Mr. BRAINE-HARTNELL (Cheltenham) read notes on a case of a hydatidiform mole which he removed from an unmarried girl by hysterectomy. When he saw her she had been bleeding for some time, and was profoundly anaemic. There was a mid-line elastic swelling reaching half way to the umbilicus, but there were no other signs of pregnancy. After a stormy convalescence she made a good recovery from the operation, and had since married and had one child.

#### *RIPENING OF THE GRAAFIAN FOLLICLE.*

A MEETING of the Edinburgh Obstetrical Society was held on March 13th, the president, Dr. HAIG FERGUSON, being in the chair, when Dr. WILFRED SHAW described the histological changes in the Graafian follicle during the process of ripening.

Dr. Shaw said that through the action of special mechanisms the enlargement of the follicle proceeded towards the surface of the ovary, and the discus proligerus rotated so that immediately prior to ovulation it lay beneath the spot which was subsequently to become the stigma. An account was given of the histological appearances at the stigma immediately before ovulation, and also after rupture of the follicle had taken place, and the methods of permanent closure of the stigma were described. Some distortion occurred in the outline of the follicle after ovulation, but there was no effusion of blood into the cavity of the follicle, because at this stage the granulosa layer was not vascularized, and the engorged theca interna layer was shut off from the granulosa layer by the membrana limitans externa. In the development of the corpus luteum from the follicle the granulosa cells hypertrophied and gave rise to the large lutein cells. The theca interna cells persisted at the periphery as the paralutein cells. The convolutions of the corpus luteum were produced through the enormous growth of the granulosa cells, aided by

capillary tufts, which grew up from the theca interna layer. The method of determining the time relations between ovulation and menstruation was then described. It consisted in the accurate histological examination of both ovaries of women with normal menstrual cycles; in these cases the dates of the last menstrual period and the day of the cycle when the specimens were obtained were known. It was found that recently ruptured follicles and proliferating corpora lutea were demonstrated only after the sixteenth day of the cycle—the first day of the menstrual period being taken as the first day of the cycle—while until the thirteenth day of the cycle only retrogressing corpora lutea were found, although, in cases corresponding to the post-menstrual phase, ripening follicles were also present. It was concluded that ovulation took place between the thirteenth and sixteenth days of the menstrual cycle, in healthy women constantly without gross variations in time, and that it occurred rhythmically once a month. Further indirect evidence in support of this view could be obtained by observing the earliest time in the cycle when premenstrual changes appeared in the endometrium, for there was good evidence that the corpus luteum produced these premenstrual changes.

The corpus luteum produced from the first follicle to rupture inhibited further ovulation; the remaining ripening follicles in the ovaries underwent atresia, and ultimately gave rise to the interstitial cells. Occasionally, in about 5 per cent. of cases, two follicles ruptured simultaneously, and two corpora lutea were found in the ovaries. If both ova were fertilized binovular twins resulted. Ovulation did not occur before puberty or after the menopause, for at these times no corpora lutea could be demonstrated in the ovaries. During pregnancy ovulation was inhibited although follicle ripening proceeded normally, and again, during lactation, amenorrhoea was determined through no corpora lutea being produced. It was pointed out that if menstruation was considered as the result of the disintegration of a premenstrual endometrium, menstruation could be distinguished from abnormal uterine haemorrhage; with this definition it followed that menstruation was invariably preceded by ovulation. Menstruation did not always follow ovulation: examples of this were seen in the case of pregnancy and in the condition described as corpus luteum persistens. The problem of the relation to conception was then raised, and it was pointed out that fertilization probably occurred only after the fourteenth day, but, since spermatozoa might survive in the female generative tract for some time after coitus, it followed that coitus might be fertile before this time. Whether coitus could be fertile after the fourteenth day depended upon the survival period of the ovum after ovulation; in human beings there was very little evidence to show what this period might be. It seemed, however, that the least fertile part of the cycle was the late premenstrual phase. Evidence was brought forward to show that the amenorrhoea met with in advanced stages of conditions such as Graves's disease, diabetes, and dementia praecox was due to an inhibition of ovulation. An account was then given of the changes in the ovaries as a result of x rays and radium used therapeutically to create an artificial menopause; it was shown that with large doses follicle ripening was inhibited, with smaller doses ovulation was inhibited, and it was concluded that the action of radiations in producing an artificial menopause was on the ovaries and not on the uterine. The changes in the ovaries in Schröder's metropathia haemorrhagica were described, and evidence was adduced that the inhibition of ovulation in these cases was due to the endometrium.

### FRACTURE OF CERVICAL VERTEBRAE.

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland on February 17th, the president, Dr. T. T. O'FARRELL, in the chair, Sir WILLIAM I. DO C. WHEELER showed a specimen consisting of the cervical vertebrae and spinal cord removed from a man, aged about 40, who had fallen from a height on to his head. Sir William Wheeler said that when the patient was

admitted to hospital there was a lacerated wound over the right temple, and partial paralysis of both legs. The knee-jerks were exaggerated; there was no Babinski sign and no ankle clonus. The pupils were small, but reacted to light; the temperature was 98.6° F., and the pulse rate 80. After the lapse of twelve hours both the motor and the sensory paralysis in the legs were complete. The right arm had become weaker than the left, but the muscles were capable of co-ordinated movements. The left arm seemed unaffected. Four hours later the right arm was helpless and the left arm weaker; the abdomen and thorax had now become paralysed. The temperature was 103° F., and respiration was carried on by movement of the diaphragm. The man was fully conscious, and it was therefore obvious that the total paralysis was not produced by an intracranial lesion. Fracture of the cervical vertebrae below the third (emergence of the phrenic nerve) was suspected. The man had several times moved his head freely backwards and forwards and from side to side; in fact, there was no limitation of movement. Spinal puncture revealed that the fluid was not under pressure and contained no blood. The condition of the patient remained unchanged for another ten hours, when he suddenly complained of headache, vomited, became unconscious, and died; the temperature then was 109° F. An x-ray photograph taken before death showed an injury in the nature of a "sprain fracture" of the fourth, fifth, and sixth cervical vertebrae, but there was no displacement. At the necropsy it was ascertained that the chief lesion was produced by hyperextension of the neck, the intervertebral discs between the fourth and fifth, fifth and sixth, and sixth and seventh cervical vertebrae being torn open. Some insignificant fragments of bone were detached; there was no extradural haemorrhage, nor was any blood extravasated beneath the meninges. The cord itself appeared intact. Sir William Wheeler thought that the trauma to the cord was analogous to the trauma produced by overstretching of the brachial plexus or of the musculospiral nerve; it was difficult to explain why the paralysis was not complete until about sixteen hours after the injury. The points of interest in the case were: (1) The suspicion that the man was suffering from a head injury—a suspicion which was at once dispelled by the presence of wide paralysis in the absence of unconsciousness. The free movements of the head in the presence of such an injury were noteworthy. (2) From the time of the injury to the man's death the pupils were contracted; this was characteristic of severe injuries in the lower cervical region. Sir William Wheeler traced the course of the sympathetic fibres from the cilio-spinalis centre to the Gasserian ganglion, and from thence to the eye. (3) The uppermost lesion in the spinal column was just below the phrenic nerve. (4) Wide variations of temperature occurred in lesions in this situation, Brodie having mentioned a patient who died with a temperature below 83° F. (5) Further examinations of sections of the cord might throw some more light on the exact pathological condition, and thus explain the gradual nature of the paralysis.

### Sarcoma of the Lung and Liver.

Dr. R. H. MICKS read notes on two cases of sarcoma of the liver; in one patient the condition was associated with a pulmonary growth, and in the other it was melanotic. Dr. LART exhibited specimens in both cases.

A man, aged 41, was admitted to hospital complaining of pain in the left side, and difficulty in breathing. Pus was found in the left plural cavity. The liver was greatly enlarged. The necropsy revealed a tumour involving the left pulmonary root, and spreading diffusely throughout the lung, in the apex of which there was a large cavity, and at the base numerous small abscesses, though there was no evidence of tuberculosis. The liver was greatly enlarged, and when fixed weighed 7 lb. It was everywhere infiltrated by the tumour in a diffuse manner. Microscopically the tumour was a small round-cell sarcoma.

The second patient, a man aged 61, when admitted to hospital, complained chiefly of epigastric pain, and was jaundiced; the liver was distinctly enlarged. At the necropsy a greatly enlarged liver was found which, when fixed, weighed 9½ lb. Scattered throughout it were nodules of melanotic sarcoma, mostly pigmented, though some were free from pigment. None of the other organs was involved, and no primary focus was found after a careful examination. The microscope corroborated the naked-eye diagnosis.

## Reviews.

## ABDOMINAL SURGERY OF CHILDHOOD.

PEDIATRICS is a comparatively recent specialty, and if the process of subdivision goes much further it is possible that children will before long have their own surgeons, as they now have their own physicians. Ours may indeed be an age of over-specialization, but the children's surgeon is in the unusual position of being able to call himself "general" or "special," as his fancy dictates or his company demands. At any rate, Mr. L. E. BARRINGTON-WARD's book on *The Abdominal Surgery of Children* will soon convince the ignorant or the sceptic that a wide variety of diseases may lurk within the narrow limits of a child's abdomen. The book is founded on the author's work at the Hospital for Sick Children, Great Ormond Street, and he has dedicated it to Mr. George E. Waugh, "whose generous and original mind has stimulated so many in the past twenty years." Great Ormond Street is the thread that runs right through it. The patients and the hospital museum have provided the subjects of the illustrations, and a late house-surgeon (Mr. C. A. Keogh) has contributed some excellent drawings.

The opening chapter is devoted to general principles, and might be read with profit by every doctor. The treatment of children, both before and after operation, is fully considered, and the author drives a final nail into the coffin of purgation and starvation as a preliminary to operation. Glucose receives its due weight as a therapeutic agent, and details are given of the strengths and ways of administering it. The general reader will probably begin with intussusception or congenital pyloric stenosis, and he will find much to interest him. We confess to disappointment at finding no mention of that form of intussusception—neither acute nor chronic—which seems best labelled "intermittent." Mr. Barrington-Ward believes that colopexy should be performed when an acute intussusception has recurred. He does not refer to the conception of the mobile ascending colon as a safety valve against strangulation in such patients, though any further attacks must surely be more dangerous if the habit of intussusception is not cured by colopexy. The chapter on congenital pyloric stenosis is full of good things. There are some excellent tables to show the effect on prognosis of age, weight, feeding, and length of symptoms, and the illustrations here are particularly good. The hospital series includes 310 patients, and thus provides material for an authoritative consideration of the whole subject. Results have improved from an 80 per cent. mortality in pre-Rammstedt days to about 18 per cent.; there was only one death in twenty-five patients operated upon in the first half of 1927.

The section on maldescent of the testis and its treatment is less satisfying than the rest of the book; some pronouncement on the late results of operations would have greatly strengthened it. Mr. Barrington-Ward is optimistic on the subject, though he does not seem to practise Bevan's method, which often converts an impossibility into a fairly simple proceeding. There is no mention of typhoid fever in a list of causes of enlargement of the spleen, though kala-azar and malaria appear. "Non-surgical drainage of the bile" is a riddle without an answer, and "obspitation," on page 245, is a word whose proper place, many will think, is the dictionary. However, we must not carp at such trifles when a book is so free from misprints, errors, and omissions. The exclusion of the genito-urinary system certainly leaves a big gap, but no doubt it was unavoidable in a work of this size.

The book is very well produced. There are eighty-two illustrations, each chapter has its list of references, and there is an index of names as well as of diseases. Mr. Barrington-Ward writes fluently and clearly in an agreeable manner, and we think that his book should make a wide appeal alike to surgeon, general practitioner, and student.

## NERVE TRACTS.

PROFESSOR KEILLER, of the University of Texas, has attempted a protean task in *Nerve Tracts of the Brain and Cord: Anatomy: Physiology: Applied Neurology*.<sup>2</sup> He takes for granted that the student is acquainted with the gross dissection of the brain, and proceeds directly to the anatomy of the tracts. The description of Wallerian degeneration and the clear exposition of the value of the Marchi and Weigert-Pal technique is excellent. The second part deals with the anatomy and physiology of the nerve tracts from the point of view of the clinical neurologist, and the third part deals with the diseases of the nervous system in terms of the various syndromes. The book is an attempt at filling a gap of which all clinicians are keenly aware, and represents the result of many years of teaching. Supplemented by an adequate supply of sections of the brain and cord of the normal, foetal, and diseased brain, the book provides an excellent scheme for teaching purposes. The publisher cannot, however, be complimented on the illustrations, as they are badly reproduced and calculated to exhaust the patience of the beginner who is trying to unravel the numerous complexities of structure. A bad diagram is like a bad map—it leads us hopelessly wrong.

Terminology is a bugbear, and the use of the term "telodendria" for the branching of the axones is not justifiable, as it confuses the clear distinction between axons and dendrites, which Golgi insisted upon. From the morphological point of view several of the definitions are questionable. With reference to the lower motor neurone, it is said that "the axones end in special motor nerve endings in striped muscles or by synapsing with sympathetic neurones for the supply of unstriped muscle or of glands." This contradicts Gaskell's conception of the analogy of the lower motor neurone with the cell of the sympathetic ganglion. The distinction between the sympathetic and the bulbo-sacral outflow of the parasympathetic is also omitted. The view that protopathic impulses are carried by unmyelinated fibres and epiatic by myelinated fibres is still a rash assumption. Hair-sense should not be regarded as identical with tickling, for the latter is well developed on the palms and soles. The statement that Head fails to find representation of the sixth to the twelfth thoracic nerves in the nucleus gracilis or cuneatus does not justify the author in saying that tactile discrimination and postural sense find no representation in the trunk and are limited to the limbs. Similarly, the statement that visual impressions are stored in the left occipital lobe only in right-handed persons is not based on fact. The statement that certain efferent fibres from the vermis and flocculus pass alongside the vestibular nucleus without interruption and join the vestibulo-spinal tract is in direct contradiction to Horsley's teaching that no fibres run directly from the cerebellum to the spinal cord.

There is one feature of Professor Keiller's book for which he deserves the greatest praise—namely, that he has confined himself to the human brain. Many of the recent textbooks have dealt almost exclusively with the brain of the sheep or other lower forms, to the exclusion of the brain of man. The value of comparative neurology is immense, but the medical student is not a morphologist. A considerable improvement in the standard of the illustrations should convert this first effort into a standard manual, and assure for it as great a popularity as Obersteiner's manual of forty years ago.

## PROTEIN METABOLISM.

THE regularity with which the successive instalments of Professor OTTO FÜRTH's comprehensive textbook of physiological and pathological chemistry<sup>3</sup> come to us is a tribute to the industry with which the author executes his formidable task. The sustained level of interest and critical treatment displayed in each new subject are tokens of his zeal and authority. Volume I is now complete and two

<sup>2</sup> *Nerve Tracts of the Brain and Cord: Anatomy: Physiology: Applied Neurology*. By William Keiller, F.R.C.S. Ed., New York: The Macmillan Company. 1927. (Cr. 4to, pp. xii + 455; 225 figures. 8 dollars.)  
<sup>3</sup> *Lehrbuch der Physiologischen und Pathologischen Chemie*. Von Dr. Otto Fürth. Band II, Lieferung IV und V. Leipzig: F. C. W. Vogel. 1927. (Sup. 8vo; Lieferung IV, pp. iv + 148; Lieferung V, pp. 125. 3/15 each Part.)

sections (Parts IV and V) of Volume II are now before us. This volume is to be devoted to the chemistry of metabolism, and the present parts have for their subject the metabolism of protein, purine, and carbohydrate. In Part IV we are given a full discussion of the chemistry of the digestion of protein and of the proteolytic enzymes, of protein synthesis in the animal body and of the biochemistry of urea, hippuric acid, creatine, creatinine, oxypuric acid, and the cyclic structures involved in the metabolism of the amino-acids. The concluding chapter deals with the biological breakdown of haemoglobin and its relation to the origin of the bile pigments. Part V opens with a discussion of the physiology and pathology of purine metabolism. There follow detailed reviews of our knowledge of the digestion, storage, and mobilization of carbohydrate, of pancreatic diabetes, and the role of insulin and of phloridzin diabetes. Concluding chapters treat of the biochemistry of glycuronic acid, lactic acid, and the chief fermentative processes. Professor Firth continues to display a wide acquaintance with the vast literature of his subject and an unusual ability to marshal it with a critical, yet not dogmatic, hand.

### THE LABYRINTH.

DR. BALDENWECK has incorporated nine lectures on the physiology, central connexions, examination, and pathology of the labyrinth into one volume.\* This is of a handy size, but the capacity is less than appears, because the text is printed only on the left-hand page, whilst on the right are numerous sketches and illustrations relating to points in the text opposite, just as a lecture might be illustrated by a running series of diagrams on the blackboard. It thus happens that some pages are occupied by several diagrams, others by one only, with here and there a blank page. Dr. Baldenweck apologizes for his inability to demonstrate the tests on the living subject, but the combination of clear writing, consecutive thought, and wise choice of illustrations is such as to make this of the least consequence. To ensure the necessary emphasis, to render some points perfectly clear, there are some deliberate repetitions and illustrative digressions, but these are merely the arts of an experienced lecturer. It may be said that, short of actual demonstrations on living subjects and objective specimens, these lectures are as satisfactory an exposition of a most intricate subject as it is possible to attain. The examination of the ear as an aid to the neurologist is becoming almost as much a matter of routine as the examination of the eye, and these lectures should prove of the highest assistance to instructors in otology and to those whose work brings them into frequent contact with a department of neurology. There is no clearer account, and it is difficult to imagine that there could be one, in which all the difficulties and obscure points are met by such simplicity of language and such profusion of illustrations; in short, by so complete a grasp of the subject.

### A SYMPOSIUM ON THE MIND.

THE scientific study of the human mind has probably been handicapped by the speculations and hypotheses of philosophers—social, metaphysical, and educational. The opinions of these philosophers, from Plato downwards, are scattered through a vast number of volumes, and it is by no means easy to ascertain how far their views have any physiological basis. Consequently there is great value for the general reader in the series of lectures delivered last year at King's College, London, and gathered together into one volume, with the title *The Mind*,\* under the editorship of Dr. R. J. S. McDOWALL, professor of physiology at the College. The object of the lectures was to give the public a concise general idea of the mind from several academic standpoints, and to show the complexity of the subject and the difficulty, at present, in reaching definite conclusions.

The medical man and the scientist will probably regard Professor McDowall's statement of the physiological view of mind, taken with the biological aspect described by Professor Julian Huxley, as the more rational argument, even if it be admitted that there is still much that is difficult for physiology to explain. Anyhow, the argument is more intelligible to the finite mind than the exposition of modern philosophy, as represented by Lloyd Morgan, Whitehead, and Gentile, set forth in the lecture by the Dean of King's College, the Rev. W. R. Matthews. Comprehending our inability to grasp the absolute, reality, and the transcendental ego, as expounded by Gentile, we are gratified to find that Dr. Matthews himself is unable to accept Gentile's wholesale scrapping of objectivity. There may be satisfaction to be derived from asserting that the table at which we sit has no objective existence, but that somewhere in reality there is a real table; yet for practical purposes it seems probable that greater progress in knowledge of the mind will be made by beginning at the bottom, and investigating mental phenomena as they are presented to our senses. Similarly, it seems hardly likely that much advance will be made by labelling oneself an interactionist, a parallelist, an epiphenomenalist, or any of the other brands of philosopher described by Dr. Aveling in his lecture on psychology.

When the intellectual Philistine has made an effort to grasp the meaning of the lectures given by the psychologist and the philosopher, it becomes hardly necessary to pursue investigations into the views of the educationist, the sociologist, and the aesthete. It is sufficient, perhaps, to quote a remark of Professor McDowall, "Man's conception of Mind is the greatest evidence of his conceit." The human mind has suffered from the fact that its study fell into the hands of the philosopher long before the experimental observer came into existence. It is for this reason, probably, that Mr. Collingwood thinks that when he wants a country cottage his mind creates an aesthetic something which existed previously only in his imagination.

### NOTES ON BOOKS.

THE first quarterly number of the seventy-eighth volume of the *Guy's Hospital Reports*\* has as the frontispiece the portrait of the late Professor Adrian Stokes, of whom an extremely sympathetic appreciation is given, containing extracts from his letters when with the Rockefeller Commission on yellow fever in West Africa. These show that the results obtained there throw doubt on the now generally accepted view that the disease is caused by the *Leptospira icteroides*. During his four years at Guy's as Sir William Dunn Professor of Pathology Stokes made a unique position for himself as an inspiring teacher and unfailing source of help, to whom all turned. Sir William Hale-White contributes a note on the birthplace of Richard Bright and on Bright's two earliest papers—his thesis for the Edinburgh doctorate on erysipelas in 1813, and a dissertation on gangrene read before the Royal Medical Society of Edinburgh in the same year, which is reproduced in full. Dr. G. W. Nicholson discusses the problems of heredity in the light of pathology, and concludes that potencies are transmitted, but that characters are always acquired. In his essay on hyperpiesia Dr. A. H. Douthwaite speaks highly of the therapeutic effect of venesection. In recording a case of pancreatic cyst associated with diabetes Mr. O. A. Beadle reviews the literature, and finds only three similar cases. A case of meningitis accompanying pneumonia and followed by recovery is recorded by Mr. R. L. Waterfield, and one of cut throat in a 5-months infant by Mr. N. Eckhoff. In his article on cataract Mr. Marcelli Shaw provides some interesting historical details, and analyses the results of the medical treatment of this disease. Mr. W. M. Mollison's historical account of the work of Samuel Sharp and his predecessors on the functions and surgery of the tonsils was apparently stimulated by the "Critical inquiry into the present state of surgery" by this surgeon to Guy's Hospital from 1733 to 1757.

It is not surprising that a second edition of Dr. C. L. DANA'S *Peaks of Medical History*, the first edition of which was noticed in our columns less than two years ago, has so soon become

\* *Leçons sur l'exploration de l'appareil vestibulaire*. Par Dr. L. Baldenweck. Paris: Vigot-Frères. 1928. (61 x 9½; pp. 300; 153 figures. 40 fr.)

\* *The Mind*. By various authors. Edited by R. J. S. McDowall, D.Sc., M.R.C.P.E.D. With an Introduction by Ernest Barker, M.A., D.Litt., LL.D. London and New York: Longmans, Green and Co., Ltd. 1927. (Cr. 8vo, pp. xvi + 316. 8s. 6d. net.)

\* *Guy's Hospital Reports*, Vol. 78 (Vol. 8, Fourth Series), No. 1, January, 1928. Edited by Arthur F. Hurst, M.D. London: The Lancet, Ltd. (Med. Bro. pp. 126; 2 plates, 1 figure. Annual subscription, £2 2s.; single numbers, 12s. 6d. net.)

\* *The Peaks of Medical History: An Outline of the Evolution of Medicine for the Use of Medical Students and Practitioners*. By Charles L. Dana, M.D., LL.D. Second edition. New York: P. B. Hoeber, Inc. 1928. (Demy 8vo, pp. 105; 62 illustrations. 3 dollars.)

necessary. He shows that the present state of medicine is the result not of steady progress during the four thousand years of its existence, but of the last four hundred years of scientific research and the impetus given to physiology by Harvey's discovery of the circulation. The concluding section on biographical notes ends with a graceful tribute: "Whoever knows well the writings of William Osler is an educated man."

Literary output has become so enormous that many give up all hope of keeping themselves informed of the general progress of the science of medicine. Yearbooks, indexes, and collections of abstracts are available in abundance to assist them, but a mere glance into some of these works, so laboriously compiled, is often sufficient to dispel any lingering desire to tackle the subject at close quarters. Yet it is not as extensive as it at first appears. Probably nine-tenths of the observations recorded are mere stepping-stones to some final inference, and it is the inference alone that the general reader needs to know and assimilate, the observations themselves, with their complicated technique and conditions of proof, being of interest only to those engaged in the problems to be solved. In approaching the subject this fact has to be borne in mind, and it will be found to render our course much clearer. We need as a starting point to have some dogmatic statement of the doctrine of disease, as it is generally accepted at the present time; this can be readily obtained from the textbooks. But it is indispensable that we should also be informed of the directions in which the conception of disease is tending to change, and of the existing currents of opinion. If these are known it becomes less difficult to gauge the significance of what might otherwise appear to be a disconnected series of observations. Professor G. HERXHEIMER has written a book<sup>1</sup> to help his fellow countrymen in this matter. Starting with the fundamental pathological processes—the cellular pathology, inflammation, the degenerations so called, inflammation, infection, and tumour formation—he describes the trend of opinion in these branches of medical science which he conceives to have been observable in the period 1912-26. It is a small book exhibiting considerable originality of treatment. Some of the subjects are dealt with somewhat too concisely, but if the book were expanded so as to cover the whole ground it should become a standard work. It is a model that might be copied in this country with advantage.

The object of Dr. ROBERT A. KILDUFFE's *Clinical Interpretation of Blood Chemistry*<sup>2</sup> is to make the practitioner familiar with the significance and clinical interpretation of the results of chemical examination of the blood, especially in diseases such as nephritis, hypertension, diabetes, and acidosis, which cannot be managed intelligently without such examination. The work consists of twenty-one chapters, in which the writer gives a concise account of the various chemical constituents of the blood, and then discusses the clinical applications of blood chemical analysis, the dietetic management of metabolic conditions, the calculation of diabetic diets, and the insulin treatment of diabetes. A short bibliography of recent literature, mainly American, is appended to each chapter. The work should prove a useful guide to the practitioner and senior student.

Dr. CORBET FLETCHER's *Compendium of Aids to Home-Nursing*<sup>3</sup> suffers from an attempt to compress too much information into too small a space. He endeavours to assist the digestion of this potted knowledge by means of aids to memory, so that "Nurse Spratt knew the aids to diagnosis" is meant to recall to the neophyte that she must observe the skin, pulse, respiration, attitude, tongue, and temperature of the patient. Fortunately Dr. Fletcher provides a glossary of these aids. The information he gives seems in the main to be correct and easy to follow; but when we are told that the sick-room requires a maximum of sunlight, a large air inlet, and a minimum of draughts, we are not sure of the meaning of the statement that "these requirements are satisfied by a window which allows 24 square inches per person."

The publication of the forty-fourth annual issue of the *Year-Book of the Scientific and Learned Societies*<sup>4</sup> will serve, its producers hope, to call attention to the vast amount of original work that has been done by scientific investigators. While this well-known volume has an established place as a work of reference, it is also intended to serve as an index to

the progress of science since the last issue. The societies mentioned include Government departments, and are grouped under fourteen main headings according to the branches of science concerned. Lists of contributions to the proceedings and publications of societies are given; thus mention is made of the various papers read before the Sections of the British Medical Association at the Annual Meeting in Edinburgh last year; of the papers published in the *Proceedings of the Royal Society of Medicine*; and also of the publications of the Medical Research Council and of the Lister Institute.

## PREPARATIONS AND APPLIANCES.

### TABLOID IRRADIATED ERGOSTEROL.

Messrs. BUNNONGHS WELLCOME AND Co. produced pure ergosterol in 1925, and they have just issued a tabloid form of irradiated ergosterol. Each tabloid contains 0.15 mg. (0.00015 gram) of drug, and its potency is indicated by the fact that this minute quantity is equivalent in vitamin D content to a tablespoonful of cod-liver oil. The makers point out that cod-liver oil contains vitamin A as well as vitamin D, and that probably the former is of importance in promoting resistance to infection. Since the oil contains the combined vitamins it is therefore ideal in rickets, where there is increased tendency to respiratory and gastro-intestinal infections. Sometimes, however, the rachitic condition is refractory and yields slowly to treatment, and in these cases the vitamin treatment can be greatly intensified by administration of tabloid irradiated ergosterol. They suggest, therefore, that the product should be used as a supplement to cod-liver oil in the treatment of rickets. Tabloid irradiated ergosterol can also be used in prophylaxis of rickets, and one particular method is the administration of the drug to the pregnant or nursing mother to increase the maternal supply of vitamin D.

### A PORTABLE URINE-TESTING OUTFIT.

We have received from Messrs. Reynolds and Branson, Ltd. (13, Briggate, Leeds) a small portable urine-testing outfit, which has been designed by a general medical practitioner, and is termed the "Urolyt." Although capable of fitting easily into the overcoat pocket or into a small bag, it enables albumin, sugar, acidity,

and specific gravity tests to be made, an ingenious arrangement permitting boiling up of a Fehling solution on a glass slide. It is supplied in two sizes, the larger at £1 5s. and the smaller at 15s. The accompanying illustration will give a sufficient idea of the layout.

### A BELT FOR USE IN SUPRAPUBIC DRAINAGE.

Mr. R. H. Jocelyn Swan, M.S.Lond., F.R.C.S., has devised a new attachment for use with a Hamilton Irving's suprapubic drainage box.

It consists of two pieces of flat rubber, each fitted with a buckle, to which can be attached a broad piece of elastic webbing. When applied to the elastic webbing of the box the rubber lateral supports of the box the patient's abdomen; the elastic passes over the iliac crests and forms a much more comfortable attachment than that usually supplied. The buckle on each side renders the attachment of the webbing and the adjustment of the box very much easier than with the previous strap, while the perineal straps can be dispensed with. In use it is more comfortable to the patient, and it has the additional advantage of cheapness.

The belt is made by the Genito-Urinary Manufacturing Company, 28, Devonshire Street, London, W.1.

<sup>1</sup> *Krankheitslehre der Gegenwart*. Von Prof. Dr. Gotthold Herxheimer. Dresden und Leipzig: T. Steinkopff. 1927. (6 x 8 1/2, pp. xvi + 256. R.M.12.)

<sup>2</sup> *The Clinical Interpretation of Blood Chemistry*. By Robert A. Kilduffe, A.R., A.M., M.D. Philadelphia: Lea and Febiger. 1927. (5 1/2 x 8, pp. x + 185; 20 figures. 2.50 dollars.)

<sup>3</sup> *A Compendium of Aids to Home-Nursing*. By N. Corbet Fletcher, M.B., R.Ch.Cantab. Third edition. London: J. Baile, Sons, and Danielsson, Ltd. 1927. (Demy 16mo, pp. 409. 1s. net.)

<sup>4</sup> *Year-Book of the Scientific and Learned Societies of Great Britain and Ireland, Session 1926-27*. Compiled from official sources. Forty-fourth annual issue. London: O. Griffin and Co., Ltd. 1928. (Demy 8vo, pp. vii + 416. 18s. net.)

## EPILEPSY.

## LUMLEIAN LECTURES BY DR. JAMES COLLIER.

THE Lumleian Lectures for 1928 were delivered at the Royal College of Physicians of London by Dr. James Collier, physician and lecturer on medicine, St. George's Hospital, on March 22nd, 27th, and 29th.

## THE NATURE OF EPILEPSY.

In his first lecture Dr. Collier said that he had chosen "epilepsy" as his subject because it seemed to him opportune to reconsider this symptom-complex in general in view of the new clinical facts which had been brought to light and the new conceptions of the nature of epilepsy which had arisen. He mentioned a few recent hypotheses to indicate the necessity for an analysis of the opinions held by authorities, sometimes widely divergent, with the object of producing a useful working theory.

His own argument was that the clinical phenomena met with in idiopathic epilepsy, in epilepsy from local lesions of the brain, and in the symptomatic epilepsy occurring in disordered metabolic states, general diseases, and intoxications, were identical and truly indistinguishable. Further, that those occurring in narcolepsy, migraine, vaso-vagal seizures, idiopathic syncopal attacks, and perhaps also in tetany, were phenomena of the same order, and were closely allied to those of epilepsy, with which they occasionally mixed. He believed that there was one pathological factor common to all these conditions—a metabolic dyscrasia, the nature of which was not always quite the same, so that different clinical syndromes occurred in which the prognosis varied.

So far as the so-called "idiopathic" epilepsy which affected man and the animals was concerned, no pathological changes had been found upon which any hypothesis as to the nature of epilepsy could be built. The findings had been for the most part frankly negative. Attention had therefore been turned to the possible discovery of an explanation of epilepsy in some perversion of the chemistry of life—some metabolic dyscrasia leading to the presence of substances within the system which acted upon the nervous system as did convulsant poisons, and might cause in some cases the progressive impairment of its higher functions.

The lecturer mentioned a number of experimental investigations along these lines, and referred particularly to the enticing theory put forward by Bossard that the immediate cause of the epileptic attack was "anaphylactic shock" from some product of disordered metabolism, the local effect of which was upon part of the cerebrum, while the general effect was shown by the fall in the blood pressure and the leucopenia which, Bossard claimed, invariably and immediately preceded every epileptic attack of any magnitude. Bossard's hypothesis was not contradicted by any experimental evidence, and upon it all the clinical manifestations of epilepsy could be intelligibly explained. It was a useful working hypothesis for the present. By far the most important statement was that one of the essential features of the epileptic attack was a fall of blood pressure. If this was true it was of far-reaching importance, for it did away with the hard-and-fast line of separation between epileptic manifestations and syncopal attacks which had been laid down by many authorities. Such initial fall of blood pressure, if proved to be constant in the epileptic attack, would serve, the lecturer hoped, to rid the mind of that explanation in pathology of so many ill-understood diseases—arterial spasm.

*Metabolic Disturbance the Essential Cause.*

The lecturer submitted that there were many clinical features of epilepsy which strongly supported a metabolic disturbance as the essential cause of the condition.

(1) The very common incidence in early infancy, when the personal metabolism might not be strongly organized, nor the developing brain highly stable, and the important influence which so definite a metabolic disorder as rickets might have in determining the incidence of epilepsy; also the incidence at the time of puberty, when important metabolic changes might be presumed to occur, and again a small incidence in the degenerative period of life, when

metabolic regulation might be failing. The periodicity of epilepsy also might be most reasonably explained on the grounds of a metabolic dyscrasia.

(2) The usual immunity of the epileptic woman from attacks during pregnancy, a fact only to be explained on the basis of the correction of a faulty metabolism in the mother by that of her foetus. On the other hand, epilepsy might occur only during pregnancy; this form probably belonged to the class of eclampsias due to anaphylaxis from foetal products.

(3) Status epilepticus, for which, in the lecturer's view, the only explanation was on the grounds of an acute autotoxic process. The condition closely resembled experimental convulsions from the exhibition of convulsant poisons.

(4) The immunity of the habitual epileptic from many common diseases—an immunity which he showed in common with the subjects of infantilism, idiocy, or cerebral diplegia, and which favoured the argument that in the epileptic subject metabolic perversion was a fundamentally important factor.

*Organic Epilepsy.*

The occurrence of epilepsy in connexion with every conceivable variety of local disease of the cerebral hemispheres was a difficulty in the conception of a fundamental factor for epilepsy in a disordered metabolic state. The idea of organic epilepsy as something quite apart from idiopathic epilepsy, with a different clinical aspect and etiology, had impeded progress in the knowledge of epilepsy, for there was really no difference whatsoever between the clinical manifestations of epilepsy resulting from organic disease of the nervous system and those of idiopathic epilepsy. The lecturer had himself observed every known feature characteristic of idiopathic epilepsy in cases of organic disease of the brain. He had seen every conceivable variety of local attack, both sensory and motor, occur in idiopathic epilepsy, and he was in the habit of teaching, perhaps too dogmatically, that the commonest cause of Jacksonian epilepsy was idiopathic epilepsy, but that actually was his individual experience.

There was no lesion of the brain that would certainly produce epilepsy, whatever its nature or position; on the other hand, there was hardly a lesion of the brain of any nature which had not produced epilepsy. Obviously, therefore, it was not the lesion of the brain alone which was responsible for the condition. There must be some other factor which, together with the brain lesion, could produce epilepsy. This second factor had been widely sought in many directions, but the lecturer submitted that it was in reality the same disorder of metabolism which he had already put forward as the fundamental cause of idiopathic epilepsy, but existing in minor degree, so that there were no spontaneous outbursts until the local lesion of the brain was added.

He went on to describe the experimental work of Dandy and Elman at the Johns Hopkins Institute at Baltimore, which gave some support to his idea of the unity in cause of idiopathic epilepsy, organic epilepsy, and symptomatic epilepsy. These experimentalists had shown that a local lesion of the brain, not in itself epileptogenic, could in junction with a disturbing agent in the general body circulation, again not in sufficient dose to be epileptogenic, produce both local and general epilepsy. That was the proposition, said the lecturer, which he had already advanced as a possible explanation of epilepsy as occurring from local disease of the brain.

In conclusion, he spoke of those happenings usually called convulsions, with which were found on occasion—he would not say commonly—most, if not all, of the clinical phenomena which characterized epilepsy, the clinical picture *qua* epileptic manifestations being sometimes indistinguishable from epilepsy proper. He submitted that since the train of phenomena resembling those of epilepsy was well known to occur from disordered nutritional states, from interference with important organs of metabolism, and from infections and intoxications, all of which were productive of metabolic dyscrasia, it was a fair argument that all epilepsy might be similarly caused, and that symptomatic convulsions and other epilepsy-like manifestations should be included in the epilepsy description.

## ASSOCIATED MALADIES.

In his second lecture Dr. Collier dealt with several separately described diseases which had a close affinity with epilepsy—perhaps in clinical association, or with parallel manifestations, or arising under the same circumstances. These conditions were migraine, pyknolepsy, narcolepsy, vaso-vagal attacks, syncopal attacks, and tetany. Migraine, narcolepsy, and tetany were well known to occur, as did epilepsy, from local lesions of the brain, and there seemed to be very good grounds for including all these maladies in the same clinical and pathological group with epilepsy, of which some of them might be only varieties.

Migraine was sometimes personal, but often hereditary and familial. Its symptoms might be usefully divided into two groups: (1) that of the hallucinations, paralyses, and mental states; (2) that of the headache and vomiting. He maintained that a state of lowered blood pressure was always present with both groups. The symptoms of the first group almost exactly resembled those which occurred in epilepsy, except that they were so tardy in onset and lasted for such a long time, and that the migrainous attack was never associated with convulsion. The symptoms of the second group corresponded in a less degree with the headache, vomiting, and vestibular disorientation which often followed the epileptic attack. In both migraine and epilepsy they seemed to be the result of rapid increase of intracranial pressure from actual swelling of the brain. It seemed quite clear that the two groups of symptoms in migraine resulted from two distinct processes—the first from some process nearly identical with that occurring in epilepsy, the second from local brain-swelling. The two processes might coincide, producing the fully symptomatic attack of migraine, but much more commonly the second process occurred alone, so that migraine was best defined as paroxysmal headache.

After discussing other relations between the two conditions, the lecturer submitted that migraine might be considered as a protracted form of local epilepsy, having its seat of origin most often, but not always, in the posterior regions of the brain, and having the special association of swelling of the brain which gave rise to the conspicuous headache and vomiting.

## The Parallelism with Narcolepsy.

In the remarkable condition of narcolepsy two quite different kinds of attack occurred. One was the sudden onset of apparently normal sleep, the other was the "cataplectic" attack, as it had been termed by Dr. Adie, produced always from a sudden emotion, most often of the pleasurable kind. There was no fundamental distinction between these two varieties of attack. The sudden attacks of sleep, usually without cause, might occur upon any emotion; the cataplectic attacks might occur spontaneously; and blends were met with in which cataplexy and sleep occurred together. It would appear that both kinds of attacks had their basis in a normal event, and that in narcolepsy there was no qualitative change in the reaction of the human being to his surroundings, but rather an exaggeration or misplacement of events of the normal state. Dr. Adie considered that the malady was a functional disorder of the nervous system, primarily of an endocrine disturbance of the nucleus hypophyseus and adjacent centres of the mid-brain.

The parallelism between many of the signs of narcolepsy and those of epilepsy was striking, and it was also noteworthy that there had been authoritatively advanced as the pathological explanation of narcolepsy a metabolic disorder peculiar to the individual and, alternatively, a local lesion of the nervous system. Collectively both these conditions might be given as the pathological explanation, and that was the same pathology as he was submitting as the explanation of epilepsy.

The arguments urged against the relation of narcolepsy with epilepsy were not very strong. When Dr. Adie stated his determination that the two conditions were not the same because in narcolepsy some of the attacks were reactive, whereas in epilepsy the attacks were never reactive, the lecturer had frankly to object that it had been laid down by great authorities, including Gowers, that the most frequent of all the tangible excitants of

the epileptic fit was fright, and that he had seen many examples of this. Moreover, he did not see why the multitudinous records of reflex epilepsy from almost every possible form of stimulus—like psychic, special sensory, and sensory, and occurring indiscriminately in idiopathic epilepsy, organic epilepsy, and symptomatic epilepsy—should be excluded from the class of attacks which were known as "reactive." It would seem, therefore, that narcolepsy was usually a malady *per se*, but that it was closely parallel with epilepsy in its manifestations; that it had a similar pathology in a metabolic dyscrasia and in local lesions of the nervous system, but that in some cases the nature of the metabolic change was such as to produce a coincidence of the two diseases in the same patient.

## Pyknolepsy and Vaso-vagal Attacks.

Pyknolepsy was a type separated from among the various forms of epilepsy by Friedmann in 1906 as worthy of separate description. The attack was said to be always an inhibition of the higher psychological processes lasting from five to ten seconds; the power of speech and of voluntary movement was in abeyance, but the automatic movements were retained. The lecturer argued that the contention that pyknolepsy was a disease *sui generis* fell to the ground utterly; it was, in fact, simply a variety of epilepsy. The variation in the nature of the metabolic disturbance which underlay epilepsy was responsible for the type and the constancy of the phenomena which resulted.

Vaso-vagal attacks—called *vasal* because of the conspicuous pallor of the surface and coldness of the extremities, and *ragal* because of the common occurrence of epigastric and cardiac discomfort and respiratory restriction—made up a definite syndrome which had an important bearing upon epilepsy and related conditions. He was convinced, as the result of many observations, that the pallor at the commencement of the epileptic attack and that seen in the vaso-vagal attack, the attack of migraine, and in the syncopal attack, were all due to the same cause—namely, a general fall in blood pressure. In the vaso-vagal attack there was plenty of time to determine this fall accurately. He had seen many patients with vaso-vagal attacks, and he gave details of a case in which he had observed the attack from start to finish on at least twenty occasions. But vaso-vagal attacks were not epileptic, though, like those of migraine and narcolepsy, they might mix clinically with epilepsy and were amenable to the same medicinal treatment. It would be well to follow Gowers and class them as distinct, but belonging to the same clinical and pathological group.

## Syncopal Attacks.

The lecturer had often wondered why fainting attacks had been so stringently separated as having no association with epilepsy; he supposed it was because the lowering of blood pressure was slow and prolonged enough to be so obvious, and because the syncopal attack appeared so often as an affective reaction to some very definite though often trivial cause. He held very strongly that the syncopal attack was not an epileptic attack, but that it was a phenomenon of the same order and dependent upon a similar pathology, and should be classified in the same group with epilepsy, migraine, narcolepsy, and vaso-vagal attacks. It seemed to him that the otherwise healthy people who were subject to syncopal attacks had a personal metabolic peculiarity not far removed from that which he had suggested as the underlying factor in epilepsy and the other conditions just mentioned. The fall of blood pressure so conspicuous in the syncopal attack was an essential element in all the others.

After dealing with the occurrence of convulsion in syncopal attacks, the lecturer closed with a few words on the association of epileptic manifestations with those of tetany. Tetany was certainly the result of metabolic disturbance, for it could be produced by calcium deprivation and by parathyroid extirpation, and removed thereafter by calcium administration and parathyroid feeding. In rare instances it might appear as the result of a local lesion of the brain, and a few cases were recorded in which both epilepsy and tetany so resulted. The sudden onset of general tetany was usually associated with sudden loss of consciousness, as was the general epileptic attack.

## CLINICAL FEATURES OF EPILEPSY.

In his third and concluding lecture Dr. Collier called attention to some of the clinical features of epilepsy which had a bearing upon the argument he had advanced as to the cause of the disease. Mental deterioration, though commonly met with in epilepsy, was no necessary associate of the disease. The highest mental attainments had long been known to accompany a recurring epilepsy of life-long duration. Nor did mental failure seem to have any relation either to the severity or the frequency of the epileptic attacks, and progressive mental degeneration was met with in patients in whom the attacks were neither severe nor frequent, and was absent in patients who suffered such attacks. Mental deterioration might precede the epileptic manifestations by months or years. It was certainly not caused by the occurrence of fits. In those cases which presented mental deterioration there was another factor at work besides that which produced epilepsy, and in arguing that this was a metabolic disorder it was easy to add a further such disorder, similar to the hypothetical cause of dementia praecox, in order to account for the association of mental deterioration with epilepsy in some cases.

The lecturer supported Muskens in his recent opinion that myoclonus-epilepsy was not a blend of two diseases, but that myoclonus was a characteristic manifestation of epilepsy and simply an exaggeration of jactitation, which was a common phenomenon of epilepsy. Simple paralysis was one of the essential epileptic manifestations, not dependent upon, nor in train of, any other epileptic incident; it might be the sole manifestation of an epileptic attack, just as the paralysis of migraine usually was the sole manifestation of the migrainous attack in which it occurred. He went on to describe in close detail a case which illustrated the nature of epileptic paralysis, and drew attention to the amazing effect which a strong psychic disturbance had upon even an organic epilepsy, changing the type of the attack from an infrequent and general attack to a very frequent and local one. With regard to the lowering of blood pressure, he had argued that this was a characteristic manifestation of the attacks of epilepsy and of the allied maladies referred to in his second lecture. He would not place lowering of blood pressure as the immediate cause of the epileptic attack, nor of any of the epileptic manifestations, except the blanching of the brain and the skin—though this might in truth be the real relation—but he thought it a common manifestation of the commencement of the epileptic attacks, and he wished to bring epilepsy into line with the other epileptiform maladies in which such lowering of blood pressure did occur.

*The Epileptic Processes.*

The site of origin of epilepsy seemed definitely confined to the cortex of the cerebral hemispheres; every local lesion productive of epilepsy which he had seen had been in or near the convolutions, or had been in such a position as to allow of some secondary process affecting the convolutions. Some authorities, however, held that epileptic attacks might originate from subcortical centres. They maintained their arguments rather from the standpoint that the symptoms of tonic fits were such as they would expect to result from disturbance of function in the basal ganglia, because these showed in some degree the same kind of rigidity as did basal ganglia lesions. This was very debatable ground. No one would deny that in lethargic encephalitis the strangest varieties of paroxysmal phenomena often appeared, and this disease affected the basal ganglia in particular. The lecturer drew attention at this point to the newly described symptom of epilepsy—given by Knapp—which was held to have its origin in the putamen and optic thalamus. The case described by Knapp was of the usual type of general epilepsy in a child, with fits increasingly frequent, speech slow and difficult, limbs and trunk rigid, with perversity and slow spontaneous movements, facial grimacing, and emotional overactivity. The picture came to resemble exactly that of the malady which Gowers called "tetanoid chorea," and which Wilson had now named "hepato-lenticular degeneration," in which there were conspicuous lesions in the

lenticular nucleus. The lecturer described a characteristic case of Knapp's syndrome which was recently under his care; it convincingly indicated the truth of Knapp's picture, and left it open whether the cortex or the basal ganglia was primarily at fault. There was nothing in the nature of the fits in this case to suggest anything but a cortical origin. They were local tonic-clonic fits without loss of consciousness, they could be arrested by strong voluntary effort, and they could be produced reflexly.

*Loss of Function and Release Phenomena.*

Loss of function was the most commonly occurring feature in all epileptic symptoms. So far as the highest functions of the nervous system, commonly referred to the cerebral cortex, were concerned, the phenomena of epilepsy were, with one exception, unvaryingly those of loss of function. The whole train of positive phenomena did not seem to belong to the highest levels of the nervous system, except in the occurrence of the "dreamy state" and of highly organized hallucinations of hearing and vision. The opinion was widely held nowadays that the essential element in the epileptic attack was a sudden loss of function, local or general, in the higher levels of the nervous system, and that all positive phenomena which occurred, such as hallucinations and convulsions, were of the nature of "release" phenomena in lower centres. This, which was known as Hartenberg's theory, seemed to be the best working hypothesis for the explanation of epilepsy, though its terms "inhibition" and "release phenomena" seemed inadequate physiological words appended to very obvious things, of the real nature of which almost nothing was known at present. The lecturer suggested here that if the theory of "release" was correct, some of the release phenomena, which he instanced, must be of the negative order.

*The Treatment of Epilepsy.*

The lecturer concluded with a few remarks on treatment. The less the life of the epileptic patient departed from that of the normal person the better would be the result of medicinal treatment, and the more hopeful the outlook. In every case of epilepsy where it was possible education, occupation, and recreation should continue without any restriction. Since the introduction of the malonyl-urea compounds for the treatment of epilepsy their very great value had gained universal acceptance, and luminal, which might be taken as a type of them, had largely supplanted the bromides. It had much the same effect as they had, and did not cause acne or dyspeptic symptoms, but there seemed still to be some cases which did better on bromides. Whichever drug was used, there appeared to be no advantage in administering it more than twice a day, or in employing any but moderate doses. The whole purpose of these remedies seemed to be to anticipate and prevent the fit; it therefore appeared useless to give these drugs for the treatment of nocturnal epilepsy except in single doses at night, or for diurnal epilepsy except in a single dose in the morning, or for epilepsy that occurred both by day and by night in doses both night and morning. Inasmuch as the attacks appeared at regular times, and could be aborted one hour previously by a dose of the remedy, the epilepsy could be the more successfully treated. The only other remedies which really influenced epilepsy were zinc salts and belladonna.

Status epilepticus, however, was completely resistant to the remedies just mentioned. In that condition there was the utmost necessity to preserve the bodily nutrition and strength by careful use of food, fluids, and stimulants administered from the first by the nasal tube. Any remedy which had a depressant effect, such as luminal or bromides, did more harm than good. Paraldehyde, first used by Dr. Arnold Carmichael at the National Hospital, was of signal value in the treatment of status epilepticus. It could be given in large doses, up to 8 drachms, without ill effect, and was readily absorbable from the rectum when mixed with an equal quantity of olive oil. The lecturer said that with this remedy he had saved many patients in status epilepticus when their condition was so desperate as to make him believe that without it they must have died. He recommended the use of paraldehyde in any epilepsy in which convulsive attacks were frequent.

## THE SPREAD OF MEASLES.

In the present-day immunological epoch in the history of medicine, when so many diseases have yielded the secret of their origin, and at the same time disclosed their antidote, it is matter for regret that one of the commonest infections, and one which contributes in a substantial degree to the mortality of the country, should to such an extent have baffled inquiry as to be accepted meanwhile by public health administrators as an inevitable evil. Despite the progress of sanitation and the general improvement in ways of living, measles continues in populous communities to prevail in repeated outbreaks which ultimately outstrip every effort at control, though their case mortality in recent years has happily been reduced by the growing practice of removing selected children to hospital with the object of preventing fatal complications. The solution of the problem of measles is still in early stages, and every effective contribution to an understanding of the circumstances under which the virus passes from person to person is of interest and value.

A study by Dr. James L. Halliday of the Public Health Department of Glasgow,<sup>1</sup> which deals with the occurrence of measles among young working-class children in the city during portions of 1925-26, throws light on the part which may be played by the style of housing on the spread of this disease. In the working-class quarters of Glasgow the people are housed on the tenement system, each house, usually of three or four stories, being divided up into tenements of several apartments, arranged in flats and joined by a stairway which is the common playground of the children. In Scotland the house is called a tenement and the tenement a house. The words are here used in their English senses. In one house of four stories with fifteen tenements, as the author recounts, among ten children under the age of 10 who had never had measles nine developed the disease. The infection was introduced by one school child, who infected all the others. In another house of four stories with twenty-nine tenements, twenty-six of which opened on two common stairs, while three had front doors opening on the street, among twenty-two children under 10 who had not had measles fourteen took the disease. Four of the fourteen were school children, and ten were under school age. All the three houses with front doors of their own escaped invasion. In a short cul-de-sac of seven four-story houses, including 108 tenements in all, among eighty-eight children under 10 who had not had measles forty developed the disease. Of the forty cases nine were primary; the rest were mainly infected on the stairs. In some instances the disease was introduced from schools, in others the source was not discovered; but in all three places, once measles was brought in, its chief propagation was not in the line of the family, but among the children leading the community life on the close or common stair. These structures are inseparable from

the tenement style of dwelling in the older quarters of Glasgow, which thus lies open to the charge of favouring the spread of measles.

As regards the cul-de-sac referred to, Dr. Halliday pertinently comments upon the fact that, though eighty-eight children were exposed to risk, only forty were seized, and suggests as an explanation that the forty-eight who escaped had been immunized by receiving from time to time subinfective doses of the floating virus diffused about their neighbourhood. We think this view correct. It accords with Dudley's theory of the velocity of infection, under which infective charges which fail to infect, though they wither away, yet leave their host enriched with protective antibodies. It fits in, too, with the experience of Glasgow in the measles outbreak of the winter of 1907-8—one of the largest recorded in the city—when it was shown by J. Brownlee that at the close of the epidemic all liable to attack had not been infected, since children of susceptible ages who had not had measles repeatedly came under his notice during the ensuing summer on their admission to the Glasgow fever hospitals with other infectious diseases. They were regarded then as susceptibles who had escaped; we should think of them now rather as immunes who had resisted, having been immunized by exposure to subinfective doses of infection during the course of the outbreak.

The part played by the house which is composed of tenements, as contrasted with the house which has its own front door, in producing a higher incidence of measles at the younger ages of childhood is well brought out by the figures submitted. The incidence of measles among Glasgow children under the age of 5 years was five times as great in houses composed of tenements as in new subsidized houses erected in blocks in housing scheme areas. The percentage of school children between 5 and 6 years of age who had not had measles was in tenement areas 40 and in a housing scheme area 67. The age incidence of measles at every age up to 5 was higher in industrial and poor districts consisting entirely of houses composed of tenements than in residential districts where such houses were few. These relations have a sinister significance because of the disproportionate risk of death at the younger ages. The case mortality of measles in Glasgow in the first year of life, according to figures quoted in this study, was sixty times as great as at ages 5 to 10. For Aberdeen, Renfrewshire, and Birmingham in order the corresponding figures are 25, 21, and 24—similar, though not so high.

The author of this report attributes to the houses composed of tenements which he has dealt with, and to houses of a similar type, a definite responsibility for favouring the spread of measles at early ages, when the risk of death is greatest. The self-contained house, for the safeguarding of young children from measles, is better than the house composed of tenements. All tenement houses, however, are not essentially bad. A root-and-branch policy is not called for, and tenement buildings in Scotland, of modest height, with wide well-lit passages and spacious airy staircases, may yet have a useful part to play in the hygienic scheme of things. Be that as it may, measles meanwhile remains, regulating itself by its own laws and determining the period of its recurrent outbursts by the number of immunes which it has itself created. The immunity believed to be produced by subinfective doses is short-lived; that which follows a survived attack is usually lifelong. Each successive epidemic adds an appreciable quota to the total number of immunes in the population, and protects our country,

<sup>1</sup> An Inquiry into the Relationship between Housing Conditions and the Incidence and Fatality of Measles. By James L. Halliday, M.D., D.P.H. Medical Research Council Special Report Series No. 120. London: H.M. Stationery Office. 1928. 1s. net.

from such widespread visitations as fell upon Faroe in 1846, when measles was introduced from Copenhagen, or on the Fiji Islands in 1874, when the chief brought the disease with him from Sydney.

### DIAGNOSTIC VALUE OF PAIN.

THROUGHOUT the ages pain has been looked upon almost wholly as an evil thing. Poets, indeed, have sometimes sung of it with picturesque imagery, and fanatics have inflicted it upon themselves in the hope of acquiring merit or of purging themselves of sin; but by the great mass of mankind pain has ever been regarded as an evil to be got rid of if this be possible, and, if not, to be borne with fortitude. In an age of self-medication this attitude towards pain has become intensified, and if we could put the clock back some thirty years a great many people would probably be much less inconvenienced by the fact that they would find no toxicans on the streets than by their inability to buy a bottle of aspirin from the chemist. Yet it seems clear that, if the matter is looked at philosophically and in its widest aspect, pain is in truth a blessing, and that, as Richet said, it is a fundamental factor in human progress. We need not here discuss it in its biological aspect, or go deeply into its nature, in Sir Charles Sherrington's definition, as a psychical adjunct to a protection reflex; but, looking at it within the narrow limits of clinical medicine, with which we are more particularly concerned, pain is presented to us as a sign and a warning, to be accepted with gratitude rather than endured with curses. Many a weary hour of anguish might be saved if the medical attendant could but assess correctly the meaning of a pain; and how different would be the outlook for many a patient with cancer if only the very onset of the disease were marked by the agonizing pain of angina instead of the phantom twinge that passes as a stitch!

The importance of the careful investigation of pain as a guide in diagnosis was brought prominently forward more than sixty years ago by John Hilton in his classical lectures at Guy's Hospital on *Rest and Pain*; and although the seed that he then sowed has borne abundant fruit—tended and nurtured as it has been by the patient and penetrating observations of later investigators, notably by Ross, James Mackenzie, and Head in this country—we are still impelled far too often, either by ignorance or by lack of skilful observation, to fall back on some such explanation as "rheumatism"—now, as in Hilton's day, "our favourite phantom." If progress has been slow, this is in no way due to forgetfulness in the famous school where Hilton taught, as the clinical teaching of Jacobson, the researches of Hurst, and the biological musings of Professor Pembrey have borne eloquent witness. Following in the same tradition, Dr. J. A. Ryle draws further attention, in an address which we publish to-day, to the diagnostic value of pain and the need for a more extended and intimate clinical study thereof. In this paper Dr. Ryle confines himself, for the most part, to visceral pain, but much of what he says is equally applicable to the subject as a whole; and in relating the results of his own experience and the methods with which he sets about his observations, he has much to say that should prove a help and an encouragement to others. Hilton himself laid chief stress on what he called sympathetic pain, which was practically the same thing as the "referred" or "somatic" pain of later writers, and he related many cases in which the patient refused

to accept a diagnosis that placed the origin of the pain somewhere else than at the site where it was felt; but he was far from neglecting the information to be gained by careful observation of the patient's own sensations. The important help that may be given by the sufferer's own spontaneous gesture in describing the pain is sometimes brushed rather brusquely aside by the over-zealous possessor of the latest gadget for testing skin sensation, but it is given a prominent place by Dr. Ryle, whose vivid description of the various gestures brings to mind the old Latin proverb, *Ubi dolor, ibi digitus*.

The reasons for our inability to grasp the commonest of all symptoms, and to make it the centre point in diagnosis, are only too clear. Pain is elusive, here at one moment and gone the next, and (fortunately for us) so completely forgotten, except for the fact of its occurrence, that we often have no words with which to describe it. Then, again, there are no means of measuring its intensity or of comparing pain in different subjects. What is an agony to one may be borne with comparative indifference by another—or so we say, and who shall judge the truth? Nor is pain easy to "place," and even if it can be located we know that it may be due to some far distant lesion. Authority, too, will sometimes fail us, for disease changes its ground and pain shifts with it, so that new sources of pain are constantly being added, to be confounded with those we were beginning to understand. But above all others looms the difficulty of distinguishing the pain of organic disease from functional pain. Bichat's advice to feel the pulse may be of service on those rare occasions when the patient is seen during an attack, but for the most part the observer must rely on his own unaided judgement, which may too often be at fault. Dr. Ryle suggests that the astuteness of our forebears in judging of these things—their clinical acumen—may be in danger of being lost through too great a reliance on laboratory methods, and many a good judge will agree with him; but it is open to the other side to suggest that the absence of any laboratory method in the clinical investigation of pain is, at least in part, the explanation of our lack of working knowledge. All will, at any rate, agree that it is undesirable and unnecessary to await such developments before undertaking the more intimate clinical study for which Dr. Ryle pleads.

### MEDICAL CO-EDUCATION IN LONDON.

THE question of medical co-education in London has been raised with some prominence lately in the public press, following an announcement that three of the metropolitan medical schools, which during and since the war have admitted women students to their courses under temporary arrangements, have now resolved to take men only in the future. The schools in question are those attached to Charing Cross, King's College, and the Westminster Hospitals, and in this decision they are following the course already pursued at the London Hospital and at St. Mary's and St. George's. At University College Hospital the number of women students is limited to a small figure, while the medical schools of St. Bartholomew's, Guy's, St. Thomas's, and the Middlesex Hospitals have hitherto opened their doors to men only. The effect of the recent decision would therefore be to confine the medical education of women in the metropolis to the London (Royal Free Hospital) School of Medicine for Women and, with strict limitation in respect of numbers, to University College Hospital Medical School. Thus to all intents London would revert in a few years' time to the position it held before

the war as the only great teaching centre in these islands without facilities for medical co-education. It would have been strange if this had come to pass without some public protest, or at least without a strong plea for careful inquiry. The obvious body to move in the matter is the University of London, of which all the metropolitan medical schools are constituent colleges, and no time has been lost in starting the academic machinery. At a meeting of the Senate on March 21st a motion was brought forward by Mr. Walter G. Spencer and Dr. E. Graham Little, M.P., calling for an inquiry into the position that has now arisen, and the Senate, after discussion, appointed a committee to consider the question of the medical education of women undergraduates of the University. The committee consists of Sir William Beveridge, Vice-Chancellor of the University; Professor S. L. Loney, Chairman of Convocation; Dr. L. N. G. Filon, Chairman of the Academic Council; Dr. Graham Little, Chairman of the External Council; Sir Holburt Waring, F.R.C.S., Chairman of the Finance Committee; Mr. Walter Spencer, F.R.C.S.; the Rev. Dr. W. R. Matthews, Dean of King's College; Mr. W. R. Halliday, Principal of King's College; Sir Andrew Taylor, Chairman of the Managing Committee of University College; Miss Ethel Strudwick, Principal of St. Paul's School for Girls; and Miss Margaret Tuke, Principal of the Bedford College for Women. It is by no means a simple problem that has been set before this committee. Besides the large matters of principle involved, such as the autonomy of the several medical schools, there are questions of ways and means and of supply and demand to be gone into. We must not attempt to prejudge an issue that has already been a little confused by special pleading, but we may at least express the hope that when the matter has been studied in all its bearings a working solution may emerge which will be fair and just to the medical schools of London and in the best interests of medicine.

#### GERMAN LEGISLATION AGAINST VENEREAL DISEASE.

DURING the course of last year a law dealing with venereal disease was enacted in Germany, where a campaign for reform, chequered by many incidents and reverses, had been carried on for more than twenty years. The story of this campaign and of its successful conclusion in 1927 is told by Dr. Roeschmann in the *World's Health* for March. The German Association for Combating Venereal Disease was founded in 1902. In the following year it secured the withdrawal of the restrictions on the treatment of venereal disease out of sickness insurance funds, and the patients became entitled to free medical treatment and sickness benefit. The association soon found that the campaign against venereal disease had small chance of success without suitable legislation; that existing when the association was founded was in some respects mischievous. To understand the difficulties with which the association had to deal it is necessary to turn back to the law of 1869, according to which the "free practice of healing" was legalized. This meant that any person could set up as a healer without having passed an examination to prove his professional capacity. Unqualified healers were thus able to work endless mischief among patients suffering from venereal disease. In 1913 the association took the initiative in calling a commission of experts to draft a new law, but its discussions were interrupted by the outbreak of war. They were resumed in 1916, and a bill was laid before the Reichstag a year later; it would probably have become law if this body had not been dissolved after the revolution. By this time, however, the great importance of this matter to public health had been recognized, and the Government of the period decided to enforce several of the proposed measures by an emergency decree dated December 11th, 1918. This decree was found to be inadequate, and

in 1922 the Ministry of the Interior submitted another bill to the Reichstag, which passed it the following year after a prolonged and complicated debate. On the instigation of the unqualified healers a clause was inserted permitting not only fully qualified physicians to treat venereal disease, but also other persons if they worked under medical supervision. This was simply a licence for "covering"; unqualified healers would only have to find a doctor willing to assume responsibility for their "cures," and in large towns one doctor could have lent his name to several unqualified healers. The Reichstag, which must pass every law before it comes into force, recognized the danger of this clause, and vetoed the bill. In 1925 the bill was again laid before the Reichstag, after it had been redrafted so as to prohibit treatment by the unqualified healers; they did their best to defeat the measure, but it was passed by the Reichstag in January, 1927, and the Reichstag approved it in the following month. The federal character of the German constitution requires that the legislation of the Reich shall lay down only general directions, details of administration being left to the several States. The law in question, therefore, dispenses with coercive measures as much as possible, merely requiring the patient to submit to treatment by a medical practitioner qualified to practise in Germany. It does not provide any penalty for the patient who does not immediately fulfil this requirement, since such a penalty might prevent a patient guilty of violating the law from seeking medical advice at a later date. It is incumbent on every doctor treating venereal disease to inform his patient of its character, of the danger of infection, and of the penalties for transmitting it. If a patient discontinues treatment prematurely, the doctor in charge first asks him to resume treatment, and, in the event of refusal, reports the case either to one of the venereal disease dispensaries organized by the national insurance societies, or to the health authorities, who in their turn summon the patient to resume treatment. The summons is in both cases of the nature of a reminder, and contains no threat; only when the patient refuses to answer the summons of the health authorities may coercive measures be taken, involving compulsory treatment and even a sojourn in hospital if this is found necessary to prevent infection. Treatment involving serious risks may not, however, be enforced without the patient's consent, and he may choose his own doctor. The treatment of venereal disease by unqualified persons is explicitly forbidden; so is all treatment by correspondence, as well as self-treatment based on lectures and leaflets. The violation of this law is punished not only by fines, but also, and primarily, by imprisonment. The law contains special provisions for the protection of infants and wet-nurses. Under penalty of imprisonment or fine it forbids a woman suffering from venereal disease to suckle any infant but her own. Penalties are provided for the wet-nurse who practises her profession without an up-to-date certificate stating that she is free from demonstrable venereal disease. There are also penalties for persons engaging a wet-nurse unprovided with such a certificate. Similarly, a syphilitic infant may not be suckled except by the mother unless the person in question is herself already infected; nor can an infant suffering from venereal disease be put in charge of foster-parents unless they are informed of this fact. The Government reserves the right to prohibit the sale of prophylactics until they have been examined and approved by the health authorities; this clause has put an end to the flooding of the market with worthless productions. The supervision of prostitution is materially modified by the new law, which dispenses with compulsory measures as far as possible. Police supervision is abolished, and the maintenance of brothels is forbidden. Persons providing lodgings for women over the age of 18 will not be prosecuted for pandering unless it can be proved that the

lodge has been exploited, encouraged, or forced to engage in prostitution. The medical supervision of persons suspected of being capable of spreading the disease is, however, maintained. The medical authorities may require those suspected of spreading infection to present a medical certificate or to submit to a medical examination. In the past women alone were obliged to submit to medical examination and supervision; henceforth men also are subject to the same measures under certain conditions. The supervision of women is not confined to the comparatively few persons registered by the police, but is also extended to the clandestine prostitute. It is hoped that by these means it will be possible to stamp out centres of infection more effectively than hitherto. The problem of professional secrecy is dealt with in such a way that doctors are held to be free to report infected persons to the health authorities. But, as already pointed out, it is only a patient who refuses treatment who is subject to coercive measures. Generally speaking, responsibility has shifted from the police to the medical profession, although the police have not been wholly excluded from the field; they will continue to deal with persons soliciting in the streets or committing other offences against public decency.

#### FAMILIAL HYPERTROPHIC PYLORIC STENOSIS.

The exact etiology of the so-called congenital hypertrophic stenosis of the pylorus is still a matter in dispute, but the occurrence of familial cases strongly suggests that it is not an acquired, almost accidental, characteristic. Evidence as to its familial incidence has been collected by E. J. Caulfield in America, who reported one family described by Finkelstein in which four children were affected. At a meeting of the Section for the Study of Disease in Children of the Royal Society of Medicine, held on March 23rd, Drs. E. A. Cockayne, A. Moncrieff, and W. P. H. Sheldon demonstrated some striking examples of the familial incidence of this malady. They described uniovular twins, under the care of Dr. R. Hutchison, in whom hypertrophic stenosis of the pylorus had been diagnosed and confirmed at operation in each case. These twins had been both born by a vertex presentation, with one placenta, one chorion, and two amniotic sacs. The only other child in the family was 12 months old and healthy. One twin began to vomit at 3 weeks old, and the other at a month old; both were brought to hospital within a week of the beginning of the vomiting, and Rammstedt's operation was performed in each case. The other family shown at this meeting consisted of five children; the oldest, a girl, was healthy, and the youngest, a boy aged 4 years, had shown no manifestations of the disease. Of the remaining three boys two had been successfully operated upon in early infancy for congenital pyloric stenosis, and in each the condition was definitely confirmed at operation. The other boy had suffered from projectile vomiting beginning on the twelfth day of life, but no other definite evidence of pyloric stenosis had been obtained, and the vomiting had stopped soon after admission to hospital. Here, therefore, in a family of five children, there existed one possible and two certain cases of pyloric stenosis. A. C. Strachauer<sup>1</sup> has recently stated that the condition has been found in a seven-months foetus and in the stillborn, and this indicates very strongly that it is a developmental error. Dr. Cockayne was of the opinion that pyloric stenosis is probably inherited as a Mendelian recessive, but this cannot be proved unless, in addition to the familial incidence, the condition is found to occur more often in the families of parents related by blood than chance intermarriage would account for. It is possible, too, that as children successfully operated upon since the introduction of Rammstedt's operation grow up, a better chance of observing the hereditary nature of the disease may be afforded, since

a characteristic operation scar dating from early infancy will be better evidence than at present offered by even the most definite history of characteristic vomiting cured by medical means in either of the parents of a pyloric baby. In the meantime, the recording of familial cases gives strong support to the theory of congenital abnormality as the cause of the condition.

#### SEASONAL VARIATIONS IN DISEASE.

IF "Nature hates calculators," as Emerson said, what must her feelings be towards a medical paper which includes nearly two hundred statistical curves? The paper read by Dr. C. O. Stallybrass of Liverpool to the Section of Epidemiology of the Royal Society of Medicine on March 23rd, was thus accompanied, and his subject—the seasonal variations of diseases—could scarcely have been explored with greater pains. He had even worked out curves for diseases, not commonly thought of as seasonal—for example, curves based on returns for cities as far apart as those of Scotland and of Sweden, showing gonorrhoea to be an autumn disease, and primary syphilis a winter disease with its peak in January. His main argument was that seasonal variations in disease, like the spread of infective diseases generally, depend upon three primary factors—the presence of micro-organisms, the mode of transmission, and the susceptibility of the tissues. All other factors, in this relation largely climatic, could act, said Dr. Stallybrass, only through these primary factors, and therefore were secondary. They included temperature, relative and absolute humidity, rainfall, wind, sunshine, barometric pressure, and perhaps atmospheric electricity; and, in addition, there were certain influences arising out of the effect of the season upon human activities, such as school holidays, indoor crowding in winter, annual festivals, and so forth. The paper was largely an attempt to express the effect of variations in the secondary factors in terms of the changes which these produced in the primary factors. To express the total effect of the three primary factors on the spread of infection the author chose—or coined—the term "dispersability." The effect of climatic changes, he said, was often cumulative, and this was most pronounced in the autumnal group of infections, whose seasonal occurrence could not be directly explained by temperature changes. He cited enteric fever as an example of a cumulative effect of atmospheric warmth prolonged even for months after the maximum temperature had been reached. Why should enteric fever differ from cholera, dysentery, and diarrhoea in this respect? The explanation might be that these three diseases had short incubation periods, while enteric fever was long in developing, so that, other things being equal, in enteric the number of foci of infection would be relatively slow in multiplying. An examination of the curves of dispersability showed that while cholera, dysentery, and diarrhoea exhibited single curves with maximums in May–June or June–July, enteric fever, on the other hand, had a double curve of dispersability, with maximums in April–May and in August–September. The difference between enteric and the triad of intestinal diseases just named might perhaps be something more fundamental than mere length of incubation period. The definite rise in enteric in May had been noted by other observers, but its significance had perhaps been overlooked. He had himself noticed that chronic typhoid carriers most often gave rise to other cases in their families in the spring. In throat and streptococcal infections generally it was obviously impossible to account for autumn prevalence in relation to the length of incubation period. An investigation of the curves of dispersability showed that all these presented a double or bimodal curve, with maximums in April–May or May–June, and in August–September or September–October. Carriers of scarlet fever or diphtheria appeared to show increased activity in the spring, more especially in May.

<sup>1</sup> *Annals of Surgery*, 1:27, 167.

The curve of carriers of virulent diphtheria amongst London school children in some recent years showed a double formation, with maximums in May and in October. It was customary to attribute the increased activity of the carriers to the prevalence of catarrhal complaints or colds, but there might be other factors at work. In New York, and he believed in Paris also, both scarlet fever and diphtheria had recently been spring and not autumn diseases. In New York the maximal prevalence of both diseases was in May, although the maximal dispersability was in the late autumn. Dr. Stallybrass went on to say that the effects of temperature upon human susceptibility would appear to be evanescent. The rapid rise of respiratory mortality consequent upon a cold spell soon passed away with the return of milder weather. But might there not be a certain cumulative effect of climate upon susceptibility? The discovery of vitamins which were dependent upon the action of sunlight on plants or animals suggested that a certain climatic influence—namely, deficiency of sunlight or of ultra-violet radiation—might be capable of producing such cumulative effects. But if deficiency of vitamin could reduce the resistance of the host to infection, might there not be an action of vitamin in increasing the activity of the virus? The discussion on the paper called forth two interesting contributions—one by Sir Leonard Rogers, who showed curves of certain diseases in India correlated with temperature and humidity changes, and the other by Professor Major Greenwood, who mentioned that for certain diseases the seasonal variation had become relatively greater. The difference between the seasonal maximum and seasonal minimum in scarlet fever was very much greater during a recent period than it was a quarter of a century ago. If the incidence of infective diseases was due to two factors, one entirely uncontrollable and the other removable, then the smaller this second factor became, said Professor Greenwood, the more obvious and striking would be the seasonal variation. At any rate, the seasonal variation of scarlet fever was tending to be sharper, and the same phenomenon had been noted in America.

#### A CASE OF MISTAKEN SEX.

PHYSICAL hermaphroditism in minor degrees is not very uncommon, and is mainly interesting because of the developmental problems concerned. It is generally detected early in life, and the practical difficulties associated with it are, as a rule, met before puberty. Unusual interest attaches, however, to a case reported lately by Dr. A. J. Wilson,<sup>1</sup> since the age of 30 was reached by a person with marked genital abnormalities without the occurrence of any untoward circumstances due to a male being mistaken for a female; in fact, the true sex was only discovered when advice was sought for pain in the lumbar muscles. Inquiry elicited the fact that this supposed woman had had no menstrual period of any kind, and physical examination revealed very definite male characteristics. The body was lean and muscular, and dark wiry hair covered the limbs and chest; the upper lip and chin resembled those of a dark-haired man who had shaved for several years, which proved to have been the case. The voice was guttural and broken, the pubic hair and breasts were of the masculine type, and the movements were athletic. The scrotum was small, cleft, and not pendulous; it contained two obvious testicles, and a web of skin bound down to the scrotal left a short but thick penis, which had no prepuce, but showed hypospadias, the urethra opening on the lower surface near the corona. A smaller and blind opening was present on the lower surface behind the urethral orifice, presumably the prostatic vesicle or homologous of the uterus. Micturition was performed in the squatting position. Erection of the penis had been experienced, and, during sleep, ejaculation of a whitish fluid. The patient's sexual attraction was

towards women, and the interests were those of a male. There seems to have been some doubt at birth about the sex, but the child was brought up as a girl, and until the age of 30 had shared a sister's bed. There were seven brothers and sisters, all physically normal. As regards treatment we are informed by Dr. Wilson that the sex and name were duly corrected; the patient received operative treatment for the genital malformation, and afterwards went to live in another place.

#### THE ROYAL MEDICAL BENEVOLENT FUND.

THE annual meeting of the Royal Medical Benevolent Fund was held, under the presidency of Sir Thomas Barlow, on March 22nd. The report for the year—the ninety-second—which was presented by Dr. Newton Pitt, stated that during 1927 the applications for relief had numbered 450, and that grants had been made in all but five cases. Among the grantees were 45 doctors (four of them medical women), and 177 widows and 124 daughters of medical men. The persons receiving annuities included 16 medical men, 79 widows, and 86 daughters. Altogether the number of individuals relieved was 623, at a total cost of £13,346, in which sum the working expenses represented less than 10 per cent. The income derived from subscriptions and donations amounted to £7,590, as compared with £7,250 in 1926, and from invested property to £4,857, as compared with £4,718. Among the special donations included in the year's income was £1,000 from Dr. W. Tinker (second donation), £800 from the British Medical Association Charities Committee, and £625 from the Medical Insurance Agency. Grateful acknowledgement was made of the assistance of the British Medical Association in collecting subscriptions from its members—during the past year the sum received through this channel was £1,271, an increase of £130—and in co-operating with the Fund in several cases requiring investigation and assistance. It was stated that during the year, on a vacancy occurring in the secretaryship, Sir Charters Symonds, for many years treasurer of the Fund, voluntarily undertook the work of the secretaryship for six months, partly in order to ascertain whether its volume was such as to require a whole-time or part-time secretary. As a result a part-time secretary had lately been appointed. Sir Thomas Barlow was re-elected as president, Sir Charters Symonds as treasurer, and Dr. Newton Pitt and Mr. R. M. Handfield-Jones as honorary secretaries. Besides the existing vice-presidents, who were re-elected, Mr. F. Belben, Mr. E. W. Hey Groves, Dr. J. J. Perkins, and Dr. A. B. Soltan of Plymouth were called to that office; and in addition to the members of the committee who retired by rotation, and were re-elected, Sir Charles Ballance, Mr. Hugh Lett, Sir George Makins, Sir D'Arcy Power, and Mr. Walter Spencer were invited to join the management. In moving a vote of thanks to the president and officers, Dr. C. O. Hawthorne said how fortunate the Fund was in the men who were at the head of its administration. Its president was revered by the whole profession, the treasurer had given another instance of his devotion to the Fund by his six months of secretarial toil, and Dr. Newton Pitt and Mr. Handfield-Jones were admirable honorary secretaries. Sir Charters Symonds, in reply, said that during his experience as secretary he had learnt more about the necessities of the Fund than he had ever known before. The usual votes of thanks to all the various helpers were carried, and a special vote of thanks to the British Medical Association was moved by Sir Thomas Barlow, who said that not only had the Association given material help, but had given it in a spirit which made it all the more welcome.

We regret to announce the death, on March 25th, of Dr. Hugh Playfair, consulting obstetric and gynaecological surgeon to King's College Hospital, London.

## Nova et Vetera.

### THE TUTELARY DEITY OF MEDICINE.

THE CLAIMS OF IMHOTEP.

BY

JAMESON B. HURRY, M.A., M.D.

For many centuries Asklepios has been accepted by the civilized world as the emblematic god of medicine, without any inquiry as to the propriety of conferring this dignity on him. Recent research into the history of medicine, however, has brought rival claimants into the field, and the time has come when their relative merits should be examined with a view to a general consensus being arrived at. Such a broad survey of the gods of medicine of the ancient world as has recently been published by Jayne<sup>1</sup> shows that the various nations of the ancient world have recognized innumerable gods of healing, some with a local, others with a national or even an international reputation. Among the best known may be mentioned Ea of the Babylonians and Assyrians (said to be the earliest deity associated with healing), Dhanvantari of the Hindus, Verethraghna of the Iranians, Eshmun of the Phoenicians, Imhotep of the Egyptians, and Asklepios of the Greeks and Romans.

When, however, the history of these deities is examined, the evidence of their earthly career usually proves to be of the flimsiest description; there is little more than a shadowy tradition, nothing amounting to proof that the reputed god of medicine was actually a man of flesh and blood, still less that he ever practised the healing art. The one exception is that of Imhotep, the famous vizier and magician-physician of the time of Pharaoh Zoser of the Third Dynasty.

Imhotep was born in Ankhtowe, a suburb of Memphis, on the sixteenth day of Epiphi, the third month of the harvest season. The year of his birth is uncertain, but may be assigned to about 3000 B.C., since he was a contemporary of Zoser, whose reign is believed to have begun about 2980 B.C. His father, Kanof, was a distinguished architect; his mother was named Khreduonkh. Imhotep formed part of a long line of architects, there being no fewer than twenty-three named ancestors and descendants in his pedigree who were architects, including his son Rahotep.

This versatile man Imhotep, whose name signifies "he who comes in peace," was renowned as an architect, as a sage, as an astronomer, and as chief lector priest or ritualist. But he was specially distinguished as a magician-physician, and so impressed his contemporaries that after his death he was raised first of all to the rank of medical demigod (circa 2850 B.C.), and finally to that of full deity of medicine (circa 525 B.C.). Temples were erected in his honour at Memphis, Philae, and elsewhere, to which flocked patients from far and near, many of whom returned to their mud hovels on the banks of the Nile full of gratitude for the gift of healing that had been bestowed on them. His worship lasted till about A.D. 550—that is, a few years before the conquest of Egypt by the Moslems.

Thus in Imhotep we have, not a mere mythical creation of the imagination, but a definite and specific personality, of whom many historical details have survived—a beloved physician who ministered to his sick and suffering fellow countrymen, and who has left behind him the memory of a well-spent life devoted to the public weal. The famous Step-Pyramid, familiar to every tourist who ascends the Nile, remains as a striking memorial of his architectural

skill. There also survive many statuettes representing him as a medical demigod, as well as bas-reliefs on temple walls representing him after full apotheosis. The accompanying engraving, which is taken from a wall painting in a temple at Philae,<sup>2</sup> shows him in the stage of full deity of medicine, carrying the usual emblems of divinity—namely, the *ankh*, or sign of "life," which is carried in the right hand, and the sceptre of power in the left hand. On the grounds of priority, of nobility of character, of brilliant services to his country, and of an enduring reputation as a healer of disease, Imhotep has strong claims to be recognized as the patron spirit of medicine, as the emblematic god of our ancient profession.

In view of such overwhelming qualifications it seems on first thoughts strange that Asklepios has for centuries been accepted by the civilized world as the deity of medicine, and it is interesting to inquire how he attained to this dignity. His cult appears not to have extended much further back than the time of Homer, who is believed to have lived about the year 850 B.C. Although Homer speaks of Asklepios as a "blameless physician,"

*ἰατρός ἀμύμων*, and the father of two heroes, Makhaon and Podaleirios, who were physicians in the Greek camp at the siege of Troy, most historians assign him a mythical origin, and describe him as the son of Apollo and the nymph Coronis, who was educated by the centaur Cheiron, and instructed by him in the art of healing disease. Yet other authorities assert that Asklepios never existed as a man of flesh and blood; but was merely the personification of certain ideas. However this may be, we know that in the course of time remarkable recoveries from disease became crystallized round a real or fictitious personality, who was afterwards apotheosized by grateful humanity. Numerous temples were erected in his honour in Greece and elsewhere, the oldest one being at Trikka in Thessaly, while others were at Epidauros, Cos, and Pergamos. The cult of Asklepios gradually spread all over Greece, and became so popular that by the time of Alexander the Great between three and four hundred temples were dedicated to this deity of medicine. It was introduced into Rome at the time of the great plague early in the third century B.C., and from that period onward gradually extended throughout the civilized world, Asklepios

Imhotep as Deity of Medicine.

being accepted as the emblematic god of medicine, the reputed healer and consoler of men. His figure appears on countless statues, charters, diplomas, coins, and seals associated with hospitals, medical schools, and societies throughout the world.

The neglect of Imhotep is doubtless attributable to the fact that Western civilization has been nurtured on the literature of Greece and Rome. Not till Young and Champollion deciphered the hieroglyphs about a century ago was the history of ancient Egypt revealed to the learned world. Now that Imhotep has emerged from the mists of antiquity as the first physician whose biography has descended to us, the time has surely come when justice should be done to this Egyptian deity. To him unquestionably belongs the highest place in our hagiology; to him should physicians all the world over look up as the patron spirit of the *ars medendi*, as the emblematic god of medicine. His portrait should become the badge of our profession.

Apart from the strong historical claims of Imhotep to occupy the throne so long the seat of Asklepios appears the desirability of having as our figurehead a specific human personality, a man of flesh and blood, instead of one of uncertain and probably mythical origin. Of the life and work

of Asklepios scarcely anything is known, whereas of Imhotep there remains at least one striking architectural monument as well as numerous epigraphical and papyric inscriptions, statuettes, and mural representations,<sup>1</sup> all pointing to a distinguished and well-spent life, devoted in part to public service and in part to the healing of the sick. In selecting Imhotep as its tutelary deity the medical profession would erect on its pedestal of honour a most distinguished Egyptian who for many centuries before our era had been worshipped as the deity of medicine.

## THE STUDY OF MENTAL ABNORMALITY.

PROLEGOMENA TO THE ESTABLISHMENT OF A NATIONAL  
LABORATORY FOR THIS PURPOSE.

BY

W. R. D. FAIRBAIRN, M.A., M.B., CH.D.,

DIPLOMA IN PSYCH. ED.,

LECTURER IN PSYCHOLOGY, UNIVERSITY OF EDINBURGH.

In the *British Medical Journal* of January 14th, 1928, there appeared a plea by Professor R. J. A. Berry of Melbourne in favour of a national laboratory for the study of mental abnormality. This project deserves encouragement from all interested in the welfare of the Empire, and it is to be hoped that before many years elapse the proposal may have aroused sufficient interest to make its realization a reasonable expectation. For some reason the study of mental abnormality has conspicuously failed to fire the imagination or enlist the support of the British public. This fact is all the more remarkable in view of the appeal which this study appears to make to the citizens of the United States. There the subject is not only held to be important, but receives practical support; here neither general interest nor support is forthcoming. In consequence there is no institution in this country really comparable to the Psychopathic Hospital in Boston. It is true that in London, through the generosity of the Commonwealth Fund, the problems of mental reactions in children are about to be attacked on a large scale, but even here the impetus appears to originate in the United States.

In view of this unsatisfactory state of affairs Professor Berry's plea comes none too soon, and ought to be a trumpet call to others who share his desire to see a national disgrace removed. While, however, the establishment of a national laboratory for the study of mental abnormality is an urgent need, the proposal would be incomplete without further discussion of the lines upon which it ought to be established. Many who have read Professor Berry's plea will agree with me that the basis upon which he would have it established is too narrow to ensure its being of optimum value to the community. It is true that, when he deplores the lack of co-operative effort between non-correlated specialties in the past and advocates unity of study in the future, he lends an apparent atmosphere of breadth to his proposals. To discover how essentially narrow they are, however, we have only to ask how this unity of study is to be achieved. Though it is never explicitly stated, the general trend of Professor Berry's paper leaves the reader no doubt as to the answer which he would give. Towards the end of his paper he makes the following definite statement:

"The first place to seek for mental abnormality of all kinds, and certainly those which are commonly classified as antisocial, are the cells of the human cerebral cortex, and this study demands co-operative national effort. That there has not hitherto been any co-operative effort to study the mental abnormalities appears to be due to a lack of appreciation of the simplicity of the great principles underlying the construction of the vertebrate neuraxis."

He represents the study of the nervous system at the present day as being illogically divided between neurology and the psychological sciences on an anatomical basis; neurology is represented as concerning itself with the

receptor and effector neurons, psychology and psychiatry as concerning themselves with the internuncial neurons in their normal and abnormal functioning respectively. He then goes on to make this statement:

"To divide a functional entity, like the neuraxis of man, into a series of watertight, non-correlated specialties appears to be unscientific and calculated to breed error. It is rather unity of study which is so essential."

As the earlier and greater part of Professor Berry's paper is devoted to the interpretation of human conduct in terms of neurons and their development, it would seem that he believes unity to be best attained by substituting for all the partial, non-correlated specialties the study of the physiology of the nervous system. It is presumably to this study alone that, in Professor Berry's view, the proposed national laboratory is to be devoted. It is with the object of drawing attention to the dangers of a spurious attempt at comprehensiveness in the study of mental abnormality, and in the hope that discussion will favour the adoption of a genuine comprehensiveness, that I submit the following observations.

I. The functional entity to be studied in problems of mental abnormality is not the neuraxis of man, but man himself as a psycho-physical organism. If it is unscientific to study the receptor and effector neurons in isolation from the internuncial neurons and vice versa, it is at least equally unscientific to isolate the neuraxis from the rest of the organism. The neuraxis has definite functions to fulfil, but it is no more a real functional entity than the liver. The neuraxis may, indeed, be considered for purposes of science in relative isolation—as, indeed, neurology does consider it; but, if we desire to establish a comprehensive science, the functional entity with which we shall concern ourselves will not be the neuraxis, but the organism. That the neuraxis is meaningless apart from the rest of the body is evident when we ask ourselves what significance the neuraxis has for mental abnormality in isolation from the endocrine organs. Professor Berry has made the interesting statement that "75 per cent. of those antisocial reactions against which society seeks to protect itself, and known as 'crimes,' are directed against the person or the property—sex and acquisition." But what meaning can we ascribe to crimes of sex in terms of a neuraxis conceived apart from the gonads? What significance have crimes against property, or the steps taken by society to prevent them, if we regard the neuraxis in isolation from the pituitary and adrenal glands?—the former intimately associated, as it is, with the disposition of self-preservation, and the latter, as Cannon has shown, with the disposition of self-preservation, attack and defence. Further, if the neuraxis is physiologically meaningless in isolation from the rest of the body, it has even less meaning when divorced from psychological processes. Antisocial reactions are completely unintelligible in terms of brain cells alone. They can only be adequately understood if we introduce the psychological conceptions of instinct, motive, and purpose. The crime of rape is not simply the failure of a few pyramidal cells to inhibit the functions of the infragranular cortex; it is also the behaviour of an organism whose sexual impulses have not been subordinated to the social sentiments in the process of development. Of these two ways of conceiving it the latter is the more significant and the more fruitful. If, then, we are seeking a real functional entity on which to base a comprehensive science of human behaviour, whether normal or abnormal, there is only one such entity to be found—the entity which behaves, and this is nothing short of the human psycho-physical organism.

II. Since the functional entity in all behaviour is the psycho-physical organism, it follows that neither physiology nor psychology, nor any other science that considers but one aspect of the organism, can claim to offer a comprehensive study of either normal or abnormal reactions. In actuality no such unifying science exists; if it did, it would partake of the nature of biology. Doubtless such a science will eventually be elaborated; but in the meantime there are insufficient data for this establishment. Such data can only be accumulated at the present stage of knowledge by allowing the various biological sciences to work unrestrictedly in their own fields, and to compare their various findings with one another. This being so, division of the field between the various special sciences is not a matter for regret. On the contrary, the advance of modern knowledge has been characterized by a multiplication of partial sciences. Only by restriction of the

field can advance in knowledge take place. The history of science is the history of the birth of new sciences. The finitude of the human mind necessitates increasing specialization as knowledge accumulates. Even two thousand years ago it was only possible for Aristotle to cover the whole ground of human knowledge because he was the greatest genius in history. To-day it would be impossible even for him to compass the field of human behaviour, which, for purposes of study, is divided between various partial sciences. Comprehensive study of human reactions is not to be obtained by substituting for the individual sciences, like neurology and psychology, one single science, but by correlating the results of individual sciences with one another. The study of mental abnormality is therefore most likely to be furthered by allowing physiology, neurology, psychiatry, psychology, and other biological sciences to pursue their own goals independently, and by then attempting to relate the various results obtained in each field with one another. To attempt to obtain comprehensiveness in the study of mental abnormality by allowing the physiology of the nervous system to usurp the fields of the other biological sciences would be a procedure at once retrograde and barren of results. To devote a laboratory to such an attempt would be of little value to the community.

III. Assuming that the various sciences capable of throwing light upon the problems of mental abnormality are to be allowed to proceed unrestricted in their own fields, we must be careful to see that the various fields are properly delimited and the boundaries between them accurately drawn; otherwise clarity of thought is impossible, and confusion is the inevitable outcome. An allocation of the field such as that which Professor Berry believes to exist at the present day is above all to be avoided. If the boundaries were actually drawn where he believes them to be drawn there would be some justification for his advocacy of the physiology of the neuraxis as final arbiter in questions of abnormal human reactions. Fortunately the fields are not delimited in the manner which he represents. According to Professor Berry, neurology concerns itself with the receptor and effector neurons of the neuraxis, and psychology and psychiatry concern themselves with the internuncial neurons in their normal and abnormal aspects respectively. The unifying science whose cause he pleads would, on the other hand, concern itself with the whole neuraxis as a functional entity. The science which concerns itself with the neuraxis as a whole is, of course, the physiology of the nervous system. As regards the other sciences concerned, the boundaries are in reality drawn as follows. Neurology restricts its outlook, for clinical reasons, in two respects: it restricts itself to the neuraxis in isolation from the rest of the organism, and it further restricts itself to the consideration of the neuraxis in its anatomical aspects so far as these are affected by disease. Psychology takes as its subject matter not the internuncial neurons, but the psycho-physical organism as a whole. It restricts itself, however, to one aspect (not part) of the organism—namely, the normal behaviour of the organism so far as that can be interpreted in terms of mental process. Psychiatry resembles psychology in concerning itself with the behaviour of the organism interpreted in terms of mental process, but, being a clinical science, it has a narrower field, and, for practical reasons, restricts itself further to such abnormal behaviour as indicates a gross lack of adaptation to reality. Physiology (which, so far as it is neurological, Professor Berry would set up as the comprehensive science) resembles psychology in that it adopts as its subject matter the behaviour of the whole organism, but it differs from psychology in excluding those aspects of human behaviour which can be interpreted in terms of mental process, and restricting itself to those aspects which can be interpreted in physical and chemical terms only. Within the boundaries indicated each of the sciences concerned is entitled to complete autonomy, and is justified in attempting to push its conclusions as far as they can be carried without inconsistency. Any attempt, however, on the part of one of these sciences to usurp the field belonging to another is to be resisted in the interests of consistency and clarity of thought. To claim for the physiology of the nervous system the right to annex or even to establish a protectorate for the charge of the genuine science is to make a claim which will not bear examination. Any laboratory for the comprehensive study of mental abnormality which may be established in the future must therefore be prepared to admit to its precincts every science which is able to

make a significant contribution to the solution of the problems of the subject.

IV. Lastly, attention must be drawn to the futility of any scheme for the study of mental abnormality which fails to recognize the claims of the psychological sciences. There is an unfortunate tendency in some medical circles to depreciate the psychological in the interests of the physiological sciences. Since modern medicine is based upon physiology it is easy to see how this tendency arises, but the result is an unnecessary impoverishment of medicine. The belief that the first place to seek for mental abnormality is the cells of the cerebral cortex appears to be bound up with wrong conceptions of the provinces of the various sciences such as have already been discussed. It is, of course, quite legitimate for the physiologist to seek a solution of the problems of mental abnormality in terms of the cells of the cerebral cortex, if such a solution is consistent with other physiological facts; but it is equally legitimate for the psychological sciences to seek a solution of these problems in terms of mental processes. Both attempts are legitimate; but a survey of the last twenty-five years suggests that the remarkable advance which has taken place in the understanding of mental abnormality during that period has derived its impetus mainly from the side of the psychological sciences. Certain contributions have undoubtedly been made by neurological physiologists. The work of Pavlov and his followers may be cited as evidence of work in the physiological field which has thrown light upon the problems of human reactions, and theories of the psycho-neuroses have been elaborated which make the "conditioned reflex" the basis of their explanations; but the conception of conditioned reflexes only explains human conduct in a superficial way, and, in any case, it really offers no explanations that have not already been elaborated in terms of psychological conceptions. The work of Pierre Janet and Henry Head might also be legitimately cited as having received its inspiration from the direction of neurological physiology. The great value of Janet's conception of dissociation and of Head's work upon the problems of sensation and of aphasia is indisputable, but it is a question how far this is not to be attributed to the fact of their bringing psychological conceptions to bear upon the problems before them. This is particularly noticeable in the case of Head's researches on aphasia, which have thrown a flood of light upon a field rendered barren and obscure by a succession of workers dealing with narrow anatomical and physiological ideas. In the case of Janet the influence of psychological conceptions is also noteworthy, and the further interesting fact appears that not only the value, but the limitations, of the dissociation theory depend upon his psychological ideas. The limits of Janet's views are the limits of his sensationist psychology. It is the abandonment of sensationist psychology and the adoption of a dynamic psychology that has led in recent years to such advance in the understanding of mental abnormality. For this application of dynamic psychology to the facts of mental abnormality credit is mainly due to the psycho-analytic school.

The liability to errors, which an attempt to understand human behaviour purely in terms of brain cells involves, may be illustrated by a statement in Professor Berry's paper. Discussing the effect of environmental stimuli upon brain growth, he says:

"If, for example, the acoustic exteroceptive stimuli be completely cut off, the child becomes a deaf-mute, with a thinner acoustic cortex and a correspondingly diminished general intelligence."

In this statement it is assumed that a failure of development of the acoustic cortex necessarily implies a corresponding diminution of general intelligence. This is just the sort of assumption to which an exclusive preoccupation with "brain cells" is liable to lead. It may be true, or it may not be true, but proof or disproof of such assumptions is only possible when the psychologist is permitted to produce his evidence also.

Reference may here be made to an investigation of the general intelligence of deaf-mute children which is at present being conducted at the George Combe Psychological Laboratory of Edinburgh University by Dr. Drever and his workers. Though the results of this investigation are still incomplete, and thus not available for publication, those so far obtained would seem to emphasize the surprisingly slight degree to which the general intelligence

of deaf-mutes is affected by their disability. Mental defect is certainly not a feature of deaf-mutism, though mental defectives naturally occur among deaf-mutes as they do among hearing children. As judged by the performance tests used in this investigation (language tests being impossible), the deaf children scored remarkably high; they proved to be retarded by less than one year of mental age, as compared with a control group of hearing children. In view of the enormous disability which a deaf-mute suffers both as regards deprivation of valuable cortex and loss of the main channel for the acquisition of human knowledge, it is a striking fact that his general intelligence should seem to be so little affected. At any rate, the results of such investigations indicate the danger of pronouncing upon questions of mental reactions, normal or abnormal, if brain cells alone are studied and psychological factors neglected.

Many instances could be quoted of problems for which consistent explanations of a psychological nature have been offered, but upon which the study of the supragranular cortex can throw little light. What explanation can be offered in terms of brain cells for the fact that a hysterical patient suffers from, for example, a fear of open places; an obsessional case from, for example, a compulsion to wash his hands every time he touches a door-handle; and a paranoiac from a delusion of persecution? Perhaps all depends upon which part of the supragranular cortex is affected by some hypothetical pathological process; but no one knows what the pathological process is, which neurons are affected, or what connexion there is between these hypothetical lesions and the symptoms. Any explanation of this sort is completely barren. Yet, for the differences between the symptoms of hysteria, obsessional neurosis, and paranoia psychological explanations have been offered which, whatever criticisms may be passed upon them, introduce order and intelligibility into a difficult and obscure field.

In conclusion, the hope may be expressed that, when the national laboratory for the study of mental abnormality comes to be founded, it will be founded upon a basis broader than the study of the neuraxis and its neurons. Moreover, every precaution ought to be taken to provide facilities for the inclusion of every science that is capable of throwing light upon the problems at issue—not excluding the physiology of the nervous system. It is in the hope that Professor Bery's most valuable suggestion for a national laboratory to study mental abnormality may not be prejudiced by too narrow a conception of its functions that the above observations are submitted to the medical profession.

## New Zealand.

[FROM OUR OWN CORRESPONDENT.]

### Hospitals and Preferential Treatment of Friendly Societies.

THE public hospitals in New Zealand are not voluntary hospitals; they are supported financially mainly by Government taxes and local rates, and are "nationalized." The larger hospitals, however, have honorary staffs. The cost of treatment in hospital averages at least 17s. a day, but adult patients are charged usually 9s. a day, although only a small proportion meet their obligations. So many bad debts are incurred that as a matter of expediency hospital boards are contracting with friendly societies—better known as lodges—for a flat rate for lodge members of 4s. 6d. a day for adults and half that sum for children. This and similar arrangements are contrary to the principle, apparently now outworn, that patients are admitted into public hospitals only because they are ill and because they are not able to pay for private medical attention and nursing. It would appear that lodges are able to bargain for discounts because of their great numerical strength. The lodges object to their surgeons sending members into hospital when they might be treated at home, but members of the honorary staffs receive no remuneration for treating these patients in hospital, and the taxpayers and ratepayers feel the strain. The sick and funeral funds of the combined lodges in New Zealand in one year have shown a surplus of nearly £200,000. In the year 1925, the last for which

the records are complete, the accumulated capital of the friendly societies in New Zealand was £3,136,237, an average per member of over £34.

### Iron Starvation in Ruminants.

A deficiency disease of special interest, and commonly known as "bush sickness," has been successfully investigated, chiefly by Mr. B. C. Aston, head of the chemical division of the Department of Agriculture. This disease has been proved to be non-transmissible, occurring in ruminant stock only when pastured on certain land on the central volcanic plateau of the North Island of New Zealand. The soil affected has been formed from pumice deposited from air and not from water. An analysis of the blood of an animal in an advanced stage of the disease shows a great deficiency of iron, but the animal can be restored to health by being given Parrish's syrup or iron and ammonium citrate, or the pastures may be top-dressed with sulphate of iron. A non-ruminant, such as a horse, may continue healthy for many years on the same food and water on which a cow will sicken and die in from six to nine months. An official report on the subject states: "The pasture is composed chiefly of red and white clovers and cocksfoot. Animals taken away for a change to healthy country and then brought back still in poor store condition may now be fattened on the pasture upon which they originally became sick. The bones of an animal dead of bush sickness show no signs of malnutrition. The facts indicate that the disease cannot be referred to chronic poisoning, and that a deficiency in some essential element in the food is the real cause. The abundance of clovers and the excellence of the diseased animal's bones preclude the possibility that the bone-forming elements, calcium and phosphorus, are deficient in the pasture. Feeding tests have eliminated all other essential elements except iron, which is found to be abnormally low in the affected soils, and in the pasture grown on them."

### Post-graduate Training for Nurses.

A post-graduate course for nurses, of six months' duration, for which a diploma will be issued, has been recently established by the Department of Health in conjunction with the University and the Wellington Hospital. Various hospital boards are awarding bursaries to enable nurses to attend the course, on condition that they enter into a bond to return to the service of the boards for a stated period. The course is intended for nurses who have completed three years' training in a general hospital and are registered in New Zealand. Its object is to prepare nurses to fill positions as administrators, tutor sisters, ward sisters, and public health nurses, and it includes principles of education and methods of teaching.

## India.

### Cholera in the Punjab.

ALTHOUGH there were only 87 deaths from cholera in the Punjab during 1926, as compared with 3,049 in the preceding year, some interesting details in connexion with this disease are reported by Lieut.-Colonel W. H. C. Forster, I.M.S., director of public health for the Province, in his annual report. In the first place, since there were no annual report. In the first place, since there were no imported cases an estimate was obtained of the cholera possibilities latent in the Punjab itself. It was noticeable that the incidence of cases during the year was scattered about the Province, and did not follow the line of infection customary in the case of epidemics which have so frequently followed the entrance into the Punjab of infected persons from Hardwar. The small total mortality is held to supply further proof of the rule enunciated by Colonel Forster—that cholera and plague are not epidemic in the same year. Since the cholera season begins in April, when plague is at its maximum, the rule gives a convenient and reliable basis on which to forecast the occurrence of cholera in non-epidemic form. Thus, in 1926, plague was severely epidemic and the occurrence of cholera was

negligible. Colonel Forster adds that, fortunately for the Province, the rule does not furnish an equally sound basis on which to forecast the occurrence of cholera in epidemic form, but he thinks it worthy of note that the greatest cholera epidemic in the Province since 1901 occurred in 1921, when the plague mortality reached the lowest recorded in these twenty-six years. Colonel Forster tells an interesting story of an outbreak of a disease resembling cholera, and of indigenous origin, in a village just outside Simla. The disease was clinically indistinguishable from true cholera, but the *post-mortem* and bacteriological findings definitely negated this diagnosis, and so the matter was referred to the police. The bodies were exhumed, but chemical examination failed to reveal the presence of any poison in them. One survivor of an afflicted family fled to a village in the Ambala district, developed symptoms of cholera, and died, his death being followed by an outbreak of so-called cholera in the village. The district medical officer of health of Ambala investigated this outbreak, but again the bacteriological findings were inevitably negative for cholera. Colonel Forster concludes, therefore, that in the Punjab there is an indigenous disease which clinically, and also as regards infectivity, is indistinguishable from cholera, though the *post-mortem* and bacteriological findings contradict this etiology. There is at present no evidence as to the real cause of this disease or the extent to which it contributes to the total cholera mortality.

#### Sanitation Measures in Connexion with Fairs and Festivals.

During 1926 no fair or festival in the Presidency of Bombay was responsible for any outbreak of epidemic disease, and some indication of the nature and extent of the preventive work which lay behind this gratifying achievement is given in the annual report of the acting director of public health, Dr. Jamshyd Munsiff. The itineraries of the various bands of pilgrims are ascertained in advance, and arrangements are made to inspect the various halting places and to provide medical supervision along the routes. Large staffs of medical officers and student assistants, with sanitary officials, are collected and distributed according to pre-arranged plans, in order to assist the local authorities. Wells are treated with permanganate solution, reservoirs are filled with sterilized water, tranches are provided for pilgrims, and cholera hospitals are opened. In suitable centres the incoming and outgoing pilgrims are inspected, ambulances are kept in readiness, and cases of infectious disease with any contacts are isolated. Refuse is carefully collected and burned, foodstuffs for sale are regularly examined, and any found unsuitable are destroyed. Specially qualified inspectors are placed in charge of the vegetable and fruit markets. Adequate provision of water is ensured—a matter of considerable difficulty in some places—and special precautions have to be taken to prevent pilgrims from bathing in the drinking water. Chlorinated water is made available for pilgrims night and day in some towns, and all storage reservoirs and cisterns are carefully and regularly sterilized. Temporary dispensaries have also been found very useful in certain towns to deal with minor emergencies and prevent more serious disease from developing. Some impression of the number of pilgrims dealt with may be gleaned from the following figures for three centres: Pandharpur (two fairs), 165,312 and 91,529; Nasik (two fairs), 58,907 and 77,574; Saundatti-Yellamma, 125,000. The numerous smaller fairs and festivals receive similar attention. Cases of various infectious diseases occurred in 1926 in all parts, though epidemics were absent, and it can easily be realized what an immense amount of sickness and suffering is prevented by this systematic scheme of prophylaxis, and how many lives are saved each year.

#### Prince of Wales Medical College, Patna.

While Sir Norman Walker was making his tour in India last year as representative of the General Medical Council he visited the Prince of Wales Medical College in Patna, which has not yet been recognized officially by the Council. He spent some days there, making a careful examination of its equipment, curriculum, and general competency. In the annual report of the work of this

institution during 1926-27 the acting Principal, Major R. R. M. Porter, I.M.S., announces that during the second year of its existence all the departments have been brought into effective action. The accommodation for biological students has been increased by one-third, and minor improvements have been made elsewhere in the buildings. A good pathological museum is being developed, and a provincial pathological laboratory is to be established, together with a department for antirabic treatment. Cultivation is proceeding of a small botanical garden for the use of students, and the museums of anatomy, pharmacology, and biology are being extended. Although the department of physiology is at present rather hampered by restrictions of staff and space, good work is in progress; a biochemist is to be appointed, and experimental work in this subject is being carried on. For instruction in practical midwifery the students go to Bangalore. In addition to the ordinary curriculum a three months' post-graduate course was conducted during the year.

## Scotland.

#### Edinburgh LL.D. Degree.

THE list of those to whom the honorary degree of Doctor of Laws has been offered by Edinburgh University contains the names of several distinguished members of the medical profession and of persons connected with it. These include Sir John Rose Bradford, K.C.M.G., M.D., F.R.S., President of the Royal College of Physicians of London; Dr. James Cossar Ewart, F.R.S., formerly Professor of Natural History, Edinburgh University; Dr. George Lovell Gulland, formerly Professor of Medicine, Edinburgh University; Dr. James Haig Ferguson, M.D., formerly Senior Lecturer in Midwifery and Gynaecology, Edinburgh University; Dr. Robert Alexander Fleming, P.R.C.P.Ed., formerly Senior Lecturer in Clinical Medicine, Edinburgh University; Dame Mary Scharlieb, D.B.E., M.D., M.S.; Dr. F. G. Donnan, F.R.S., Professor of Chemistry in the University College, London; and Mr. Henry S. Wellcome, founder of the Wellcome Research Laboratories at Gordon College, Khartoum, and of the Wellcome Bureau of Scientific Research and the Historical Medical Museum, London.

#### Glasgow Cancer Hospital.

The annual meeting of the Glasgow Royal Cancer Hospital was held in the Merchants' House, Glasgow, on March 23rd. Sir John MacLeod, Bt., presided, and among those present were Sir John Gilmour, Secretary of State for Scotland, and Sir George Beatson, senior surgeon to the hospital. The chairman stated that the ordinary income in the past year had increased by over £200, and the hospital was doing valuable work in the direction of investigation into the nature of the disease for which it provided. Sir George Beatson, speaking on the work of the year, stated that enough was known in regard to cancer to say with confidence that it began as a local malady. The hospital admitted both operable and inoperable cases in order to furnish them with the best medical skill and trained nursing that was possible. It also existed to investigate the disease, and, if possible, elicit a cure. They had come to the conclusion that for inoperable cases the best system of treatment was by irradiation with radium, x rays, or ultra-violet rays. It had been found that the ultra-violet ray treatment, rather over-praised at the present time, was being used unwisely, and that many people were even installing apparatus into their own homes. A careful study of this subject was being made in their research department. They would like to make this hospital the centre for the distribution of radium emanation in Scotland. Sir John Gilmour remarked in regard to hospitals generally that whatever changes or advances might take place the fundamental thing which they must try to preserve was the voluntary principle. The death rate from cancer in Scotland had reached a very high point, the figure being 141 deaths per 100,000 people during 1927, the highest death rate yet recorded, and second only to heart disease among causes of death.

This meeting should show the citizens of Glasgow that the malady was being dealt with as one of the problems facing the country which could at least be mitigated. He believed that research was essential if they were to make progress, both in regard to hospitals and disease, as well as in many commercial enterprises. He was glad to know that progress was being made in cancer research, and he thought this ought to be encouraged by everyone.

#### Discussion on Pharmacopoeia Revision.

A meeting of the North British branch of the Pharmaceutical Society of Great Britain, held in the Society's Hall at Edinburgh on March 21st, discussed the question of revision of the *British Pharmacopoeia*. Mr. Peter Boa, Ph.C., pointed out that the 1914 edition, which had been produced prior to the war, was now fourteen years old, and did not cover many new things introduced in the interval. There had been in the last *Pharmacopoeia* a drift towards a reduction in the number of preparations, and this had led to the provision of ready-made preparations for the practitioner by wholesale manufacturers. He thought that if the *Pharmacopoeia* was to regain its prestige with prescribers it would be necessary either to increase the number of preparations or, alternatively, while making the *Pharmacopoeia* a standard for drugs, there should be some official complementary book containing suitable preparations for medical use. A strong plea for the reintroduction of imperial weights and measures in the *Pharmacopoeia* was made by Mr. Henry Stout, Ph.C. Although the last edition, he said, had given only metric weights and measures, the custom was still almost universal in manufacturing, retailing, and dispensing medicines to employ the imperial weights and measures, and for these practical reasons they ought to be included in the official publication.

#### Deaconess Hospital, Edinburgh.

The annual meeting of the Church of Scotland Deaconess Hospital was held in Edinburgh on March 19th, with the Rev. D. J. Montgomery Campbell, Moderator-Designate of the Church of Scotland, in the chair. The Rev. Dr. A. Fiddes, vice-chairman of the board of management, in submitting the report, said that the hospital was in a fortunate position, because twelve months ago it had been faced with a debit balance of £1,000, while now this had been converted into a credit balance of over £550. The number of patients treated in the wards during the year had been 732, an increase of 99 over the number of the previous year. The number of surgical operations performed had been 598, while the number of out-patients had been 6,914, with attendances numbering 23,457. It was now necessary to raise £7,000 every year for its management on efficient lines. The institution was unique in Great Britain in being the only hospital carried on by a Church, and it discharged a double purpose, treating the suffering and injured and providing a training place for nurses who had the intention of taking up mission work in this country and beyond the seas. The chairman, in moving the adoption of the report, said that he knew no form of practical Christianity which was so interesting as the work done by this hospital. He was strongly in favour of the voluntary system in the management of hospitals for many reasons. He was quite sure that a compulsory hospital could not command to the same extent the best of medical, surgical, and business talent for its work. Further, it was good for the community that it should have to do this work. The relation between Church and medicine was a very old one. Hospitals, like education, had begun with the Church, and it was valuable that the connexion should, in some way, be maintained.

#### An Ancient Scottish Surgeon.

At a meeting of the Greater Edinburgh Club, held in the Synod Hall, Edinburgh, on March 14th, Mr. John Smith, F.S.A., gave an account of the career of John Naesmyth, surgeon to King James VI of Scotland and I of England. He was the son of Michael Naesmyth, Chamberlain to the Archbishop of St. Andrews, where he received his early education. Choosing the profession of a barber-surgeon, he joined the Incorporation in Edinburgh in 1588. In 1575 he had been a member of the retinue of Lord Seton,

proceeding ostensibly on an embassy to Queen Elizabeth, but actually entrusted with the perilous task of delivering to Mary Queen of Scots certain letters from the Regent in Scotland. He succeeded in his mission, although the letters were discovered afterwards, necessitating his hasty return to Scotland. Naesmyth afterwards rose to high favour with King James, but becoming involved in a plot with Francis, Earl of Bothwell, he had to retire to France, where he stayed for about six years, and was appointed chief surgeon to the Scots Guards of the King of France. In 1600 he married Helen MacGrath, daughter of one of the most opulent citizens of Edinburgh, and prospered greatly. Being reinstated in favour with King James, he removed with the court to London in 1603 as court physician, and in 1604 was appointed royal herbalist for life. Dying in London on September 16th, 1613, in the fifty-seventh year of his life, his body was, by his own request, removed to Edinburgh and interred in Greyfriar's Kirkyard, where a handsome monument still marks his resting place.

## Correspondence.

### GLAND GRAFTING AND INHERITANCE.

SM.—In the articles headed "Gland grafting" (p. 510) and "Voronoff's experiments on the improvement of livestock" (p. 505) in the *British Medical Journal* for March 24th it is suggested that Dr. Voronoff's claim that the improved characteristics which, according to him, appear in the offspring of "decrepit and infecund males" who have been rejuvenated by implantation on their testicular tissue of portions of the corresponding tissue from young and healthy adult males, and which in turn are transmitted to their offspring, "involves the acceptance of the hypothesis of the inheritance of acquired characteristics." Even assuming there is truth in Dr. Voronoff's claim that there is an increased production of mutton and wool, for example, in the progeny of rejuvenated rams, this surely does not prove that an acquired characteristic has been inherited. An acquired characteristic, in the strict biological sense, is some alteration in the somatic cells caused directly by the environment. The appearance in offspring of a characteristic resulting from the action of the environment upon one or other of the two conjugating gametes is not, I submit, a transmitted acquirement.

The main principle underlying Dr. Voronoff's experiments would appear to consist in the replacement or reinforcement of the senile by virile testicular tissue. Where the new glandular material reinforces the physiological action of the old glandular tissue there is merely a revivification of a waning reproductive power. Where, however, it replaces the old tissue the position is more complex, but even so does not, I think, necessarily involve acceptance of the hypothesis of the inheritance of acquired characteristics. My point may be elucidated with the case of the bull Jacky, who, when 17 years old, was discarded as useless for breeding purposes. This bull, whom we will call "J," was grafted with a piece of the reproductive gland of a virile bull "V." After the operation "J" is said to have sired nine calves. Now, if this was so, surely it follows that, since the gametes of "V" have surely taken the place of those of "J," the calves are the offspring, not of "J," but of "V." Biologically speaking, "J" has merely acted as protector and food provider to the gametes of "V," and has had no more participation in the manufacture of the nine calves than a gardener has in the production of cucumbers that have grown in his frames as a result of his transference of pollen from the stamens of the male to the stigma of the female flower. Any improved characteristic appearing in the progeny begotten through "J's" mating activities are received from "V," are germinal (blastogenic) in nature and not acquired.

The case is paralleled by an experiment of Boveri. He removed the nucleus from the virgin egg-cell of a sea-urchin (*Echinus microtuberculatus*) and then fertilized it with the spermatozoon of another species (*Sphaerechinus granularis*). The egg-cell so treated developed into a larva with the characters of the paternal echinus only; the

main substance of the egg-cell provided nutriment for the daughter-cells, but did not transmit to them any of its parental characters. It should be stated, however, that Boveri's experiment has been severely criticized. Perhaps a better illustrative parallel is to be obtained by a consideration of the reproductive capacities of the scion twig used in plant grafting. The bud, which contains the germ cells, when inserted in the bark of a different variety of plant, reproduces the kind of flower or fruit that characterized not the tree or bush on which it now grows and of which it forms a part and from whose sap it draws its food, but the tree from which it was originally taken.—I am, etc.,

CHARLES M. BEADNELL,  
Surgeon Rear-Admiral.

Aberystwyth, March 25th.

#### THE NEW PORTRAIT OF JOHN HUNTER.

SIR,—With reference to the "new" portrait of John Hunter, Mr. Buckston Brownie (*Journal*, February 25th, p. 325) corrects an error made by Sir Arthur Keith as regards Christie's catalogue, but in doing so suggests that the name "Seton," to whom the portrait is there attributed, was either fictitious or that of a quite unknown man.

Before this letter appeared the error had already been pointed out to me. Seton, or Seaton as I understand it is more usually spelt, was a known portrait painter of Hunter's time, as will be seen from the following extracts from recognized authorities.

*Graves's Dictionary of Artists*.—Seaton, John Thomas. ? Seton. Exhibited 13 Portraits at the Society of Artists and 3 at the Royal Academy between the years 1761-1777.

*Redgrave's Dictionary of Artists*.—Seaton, John Thomas. Portrait painter. Pupil of Frank Hayman, studied in the St. Martin's Lane Academy, also a member of the Incorporated Society of Artists. He exhibited half-length portraits at the Royal Academy in 1774. He was practising in Edinburgh about 1780, and was in high repute, which his works merited. He was living in 1806.

*Bryan's Dictionary of Painters and Engravers* (edit. 1889, vol. ii) gives a similar account of Seaton.

As to the remaining question—by whom and on what authority the portrait was attributed to Seaton—I have the following information.

Mr. Martin of Christie's, usually responsible for drawing up the catalogues, and a recognized authority on pictures of that period, states that the pictures of Mr. McCormick came to them all labelled according to the owner's own attribution and description. Although Mr. McCormick may have told his friends he thought the portrait of Hunter was by Gainsborough, he evidently did not consider it worthy of being labelled as by that artist. The McCormick pictures consisted of 157 lots, several of which consisted of two or three pictures, and formed a full day's sale, but they only realized between £4,000 and £5,000. Mr. Martin added that the picture was very unlikely to have been by Gainsborough, or it would not have been passed over by the expert dealers.—I am, etc.,

Egham, March 23rd.

CECIL F. BEADLES.

#### BRITISH DOCTORS IN MADEIRA.

SIR,—Opposition to the presence of British doctors in this island has now been ended by a generous concession from the authorities at Lisbon by which the *modus vivendi* established with me sixty years ago is respected and amplified. I enclose a copy of a telegram from our Ambassador to Portugal showing fully the privileges conferred on us. We are by no means unmindful of your assistance in the *Journal* contributing to this happy issue from our difficulties.—I am, etc.,

MICHAEL GRABHAM, M.D., F.R.C.P.

Madeira, March 20th.

\*\*\* The telegram to which Dr. Grabham refers is addressed from Sir Lancelot Carnegie, British Ambassador at Lisbon, to the British Consul at Funchal, and repeated to the Foreign Office. The position has been the subject of discussion between the Ambassador and the Portuguese authorities following a report that a threat had been made to expel from Madeira foreign doctors who were practising there without being legally qualified to do so (*Supplement*, August 20th, 1927, p. 118). Dr. Grabham explained the position in a letter published in the *Journal* on September

24th, 1927 (p. 566). The telegram defining the Portuguese Government's attitude reads: "Permission granted for British physicians and surgeons to attend foreigners living in and visiting Madeira. They must exhibit their diplomas to inspector of health at Funchal."

#### MIDWIVES AND ANTE-NATAL WORK.

SIR,—The letters by Professor Louise McLroy and Dr. Malcolm Donaldson (March 17th, p. 466, and March 24th, p. 520) show an imperfect acquaintance with the rules of the Central Midwives Board which they criticize.

Dr. McLroy criticizes the Board for telling a "nurse" to "examine the heart with a stethoscope." Will she kindly quote the rule referred to, as I cannot find it? If the foetal heart is meant it should be stated. The examination of the foetal heart is surely essential.

She also speaks of "calling in the aid of a medical practitioner in doubtful cases." Will she kindly read the rule referred to? It runs as follows: "In all cases of illness of the patient or child, or of any abnormality occurring during pregnancy, labour, or lying-in, a midwife must forthwith call in to her assistance a registered medical practitioner" (E. 20).

She also refers to "diagnosis." "Diagnosis" is not either expected or desired; the presence of "any abnormality" at once obliges the midwife to call in medical aid, and she is the only person who has it in her power to discover abnormalities in pregnancy where a doctor is not in charge of the case.

Dr. Malcolm Donaldson endorses Professor McLroy's views. I would point out that, whatever may happen in the future, a very large proportion of labours are at present attended by midwives. If midwives were now to be abolished, many women would fall back into the hands of the untrained handy-woman. The object of the rules of the Central Midwives Board is to make pregnancy, parturition, and lying-in in charge of midwives as safe as possible.—I am, etc.,

London, S.W.1, March 25th.

H. G. WESTLEY,  
Secretary, Central Midwives Board.

#### THE EXPECTANT MOTHER.

SIR,—The care of the expectant mother has become a national question, and the Queen, in her recent message to the Maternity Mortality Conference on March 1st at the Central Hall, Westminster, expressed the opinion that the time had come for concerted action. Local authorities must by now have realized their responsibilities as regards the ante-natal, natal, and post-natal care of the expectant mother, especially amongst the poorer classes of the community. No one can deny that the care and treatment deemed necessary for the well-to-do in the trying time of childbirth must be equally necessary for the poor.

It is all very well for local authorities, whose duty it is to deal with these matters, to appoint and direct educated and trained women to go round or instruct in the clinics the people who live in the humble homes, and give advice as to what they should do and what they should not do. This, no doubt, is most excellent, but those of us who have been in medical practice for many years know to our sorrow that these poor women are not able to do as they are advised, inasmuch as they are compelled by force of circumstances to continue their home duties up to the very hour of their confinement, and to be up and about again in a week or so, or even less, doing the washing, cleaning the house, getting the children off to school, preparing the husband's dinner, and all the other responsibilities of a home. The well-to-do expectant mother can, however, rest for weeks before and after the birth of the child. It is not surprising, therefore, that our hospitals are so full of working-men's wives requiring surgical attention owing to relaxation of the tissues.

Local authorities have been empowered by Circular M. and C.W.A. of the Local Government Board, dated August 9th, 1918, to provide home helps; nearly ten years have elapsed, and how few have exercised this power! The time has come when they must wake up to the heavy responsibility which rests upon their shoulders. Home helps must be working women; they can no doubt be obtained

and paid by the local authority, to which the State can make a grant. They should take over the whole or the greater part of the housework of the expectant mother for a short time before and after childbirth, and so relieve the mother of this burden. Then, and only then, can it be expected that maternal mortality will be reduced and more healthily children be born.—I am, etc.,

ARTHUR M. BARFORD, M.D.,  
D.P.H., F.R.F.P.S.

Chichester, Sussex, March 17th.

### THE PROTECTION OF MATERNITY.

SIR,—Although we are all anxious to see a diminution in maternal morbidity, I do not think that Dr. J. S. Fairbairn's remarks at the Midwives' Institute (as reported in the *British Medical Journal* of March 17th, p. 462) ought to be allowed to pass unnoticed.

He said that "some doctors had stated that forceps were used in half the cases they attended." What doctors were these? Certainly not average general practitioners. I can understand that an occasional individual, exceptionally skilful, with very well trained assistants and a faultless aseptic technique, might use forceps where the majority of us would prefer to wait longer—and possibly rightly; but I am afraid that actually Dr. Fairbairn has been the victim of a fisherman's yarn.

However, because of this statement I have taken the trouble to look up the notes of my last 200 cases. I find that I used the forceps in fifteen cases only, and one of these was that of a multipara to whom I was called by a midwife. This, it is true, is rather more than twice the percentage which Dr. Fairbairn guesses to be that of institutions, but I do not think we can expect to get ours down to that level because of our much larger proportion of primiparae—40 per cent. in this series. I suspected five of the 200 to have subsequent genital infections. Five other patients had pyrexia due to causes such as bacilluria, mammary infection, and influenza.

I believe that these figures are in no way exceptional in general practice—in fact, I do not doubt that many doctors can show better ones—but they do suggest that the general practitioner is not the danger to his patients that our critics represent, and I like to think that the morphine and scopolamine that we can give in the first stage, and the chloroform which eases so much the last part of the second, help to justify our attendance even in cases of normal labour.

I hope Dr. Fairbairn will forgive me if I add that the necessity for accuracy is so great, and the way of exaggeration so easy, that it is difficult to be too careful when addressing an unscientific and uncritical audience; especially as this is the case when the speaker is one who is supposed to be more *au fait* with actual practice than the mere official.—I am, etc.,

London, S.E.26, March 20th.

W. M. PENNY.

### IMPORTANCE OF SPUTUM EXAMINATION IN PULMONARY DIAGNOSIS.

SIR,—Dr. Chandler's letter emphasizing the value of sputum examination is welcome because there is no doubt that this aid to diagnosis is sometimes neglected altogether, or that an insufficient number of examinations are made. Practically all public health authorities give facilities for free examination, so that there should be no difficulty about getting a patient's sputum investigated early and often.

The following points may be usefully summarized:

1. In cases with early manifestations repeated sputum examination may be necessary before the bacilli are found, although positives sometimes occur at first trial where there are few signs and symptoms.
2. The kind of case described as running its course without sputum or positive sputum includes the acute and some sub-acute types. The signs and symptoms, however, usually become distinctive before the illness has proceeded far.
3. In chronic and long-standing cases of pulmonary disease, with frequent cough and much spit, even two or three negative findings go a long way towards ruling out tuberculosis. Bronchiectasis is commoner than many people suppose, and some of its symptoms (streaked sputum, dry pleurisy, and exacerbations due to localized broncho-pneumonia) resemble tuberculosis. Asthma and chronic bronchitis may mask tubercle, which remains undetected until the sputum is examined.

4. There is no type of sputum absolutely typical of pulmonary tuberculosis; nummular sputum occurs in other diseases, and an innocent-looking mucoid drop may swarm with tubercle bacilli. So far as my experience goes, tubercle bacilli are not often found in foul-smelling sputum, and in early cases it is not usual to find them associated with large numbers of other organisms.

5. It is worth while taking trouble to obtain a good specimen for examination, and avoiding oral, nasal, and tracheal secretion, also specimens contaminated with food and tobacco. A few simple directions to the patient, and particularly instructions as to rinsing the mouth with water before expectorating into the tube, are all that is required. Two or three spits are quite enough: one does not want a tubeful.

—I am, etc.,

County of Rosburgh, March 20th. G. B. PAGE, M.D., D.P.H.

SIR,—I heartily agree with Dr. Chandler that the "absence of tubercle bacilli after many repeated examinations . . . practically excludes tuberculosis." He wisely alludes to the "pathetic constancy of the radiologist's diagnosis of tuberculosis," and we all know how "pathetically constant" that usually is—simply because they apparently dub every abnormal shadow they see in a chest radiogram as of tuberculous origin, without reference to its being evidence of an active or passive condition, or to its having originated perhaps some years previously, or to its having some other causation. This pathetic constancy is quite equalled, if not surpassed, by some zealous tuberculosis workers of to-day, who diagnose any abnormal condition they find in a chest as of tuberculous origin, basing their diagnosis upon physical signs and ignoring the fact that the physical signs of pulmonary tuberculosis are in some respects the same, and in others closely resemble those produced by a large number of other chest diseases. They thus become blind to that large and increasing ensemble which includes bronchiectasis, silicosis, chronic interstitial pneumonia, spirillosis, syphilis, and malignant disease—all producing the "damaged lung" (of Riviere), with physical signs and x-ray appearances closely resembling tuberculosis, and, as Dr. Chandler puts it, "masquerading" in its name.—I am, etc.,

B. S. NICHOLSON, M.D., D.P.H.,  
Tuberculosis Officer, Derbyshire County Council.

Chesterfield, March 20th.

### TREATMENT OF PNEUMONIA.

SIR,—I suppose the majority of doctors would agree that most cases of pneumonia are self-curative, and nothing can be done more than general good nursing; this may be true, but it is very difficult to dogmatize or to be too certain of anything in medicine. We all have our experiences with successful cases, and again, failures. I see another new remedy in the field—sodium udeinate—and some give very good accounts of it. No doubt it is a good and proper thing to write and relate our cases; in fact, it is a pity it is not a more general habit. I might say that I have treated a few cases of pneumonia very successfully with polyvalent antistreptococcus serum. I remember one case, which was secondary to a very bad septic haemid, where the first injection of the serum brought down the temperature; again, in two days temperature was mounting up, and a second injection again brought it down, and the patient recovered.

Another was a case of double broncho-pneumonia in a child about 4 years old, where I gave in one injection a whole phial of antistreptococcus serum (Parke, Davis and Co.), and had the child put into hot packs and afterwards wrapped in blankets, producing copious perspiration. I admit the treatment was somewhat heroic, and perhaps not too pleasant for the child; but anyway it proved successful, and no doubt it was a very hopeless-looking case, and much treatment had been given for days prior to this.

However, these cases are of no importance as compared to a case related in the *Lancet*, June 21st, 1913, by Sir John Byers and Thomas Houston of Belfast. Anyone reading this case will see that very often our failures are due to the fact that we do not have a correct bacteriological diagnosis.—I am, etc.,

D. HENNESSY,

Medical Officer, Bandon, co. Cork.

March 16th.

## Medico-Legal.

### ALLEGED NEGLIGENCE IN A FRACTURE CASE.

#### A JURY'S RIDER.

AFTER listening for several days to evidence in a case in the High Court in which the members of a medical partnership were the defendants, the jury took four hours to determine their verdict in favour of the doctors, and their rider points a moral which needs emphasis. The plaintiff, Mr. Henry Stroud, claimed damages from Messrs. Bates, Bates, and Wilson, medical practitioners, of St. Albans, alleging that one of the partners, Dr. Ronald Edmund Wilson, instead of treating him for a fracture of the upper part of the right femur following a motor accident, treated him for bruised muscles and strained tendons. An x-ray photograph was not taken until thirteen weeks after the accident, and that showed a fracture of the femur which had not united. The plaintiff, as a result, went to the London Hospital, and subsequently to the Lewisham Hospital, but was discharged a helpless cripple with the intimation that nothing could be done unless he consented to a major operation involving bone grafting.

Dr. Wilson maintained that from the very first he advised the plaintiff to go into a hospital and to submit to an x-ray examination, but that the plaintiff persistently refused to act on his advice, and insisted on being treated at his own lodgings. Whilst he was suspicious of many fractures in the neighbourhood of the pelvis, the spine, the sacrum, and the femur, and actually told the plaintiff that it was quite possible that an x-ray photograph would reveal one or more, Dr. Wilson found no definite symptoms. A qualified masseur gave massage for the relief of pain and stiffness for some weeks, and the plaintiff ultimately consented to have an x-ray photograph taken.

The plaintiff's story was a blank denial. He said he had never refused to submit to an x-ray examination or to go into a hospital. Dr. Wilson had never said that such refusal by him had amounted to throwing the weight of diagnosis on the doctor's own unaided judgement. Neither had the doctor said he might treat him as if there were no fractures, whereas there might be one or more. Such a conversation had never taken place. A succession of witnesses was called by both parties. On the one hand, Miss Hilda Randall said she heard Dr. Wilson say he did not think an x-ray photograph necessary; but, on the other, Mr. J. W. G. Smith, who knew Miss Randall as "Mrs. Stroud," said he heard Dr. Wilson say, "You must go to hospital for x-ray treatment," and heard Mr. Stroud reply, "I will not go into hospital on any account. Mrs. Stroud will attend to me." Dr. Wilson's version was further supported by the masseur, Mr. Gray, who said the plaintiff himself had said he refused both hospital and x-ray treatment.

The jury felt that they were entitled to better guidance than such conflicting testimony afforded in a case where a medical man's skill and veracity were questioned. Hence the rider attached to their verdict:

"We are of opinion that Dr. Wilson should have protected himself by calling in another doctor and repeating in his presence his advice that Mr. Stroud should go to hospital and submit to Roentgen rays."

Clearly, the medical practitioner whose patient refuses to take advice should at least make a definite record of that circumstance as a safeguard against the possibility of an action at law. This is a matter on which Mr. W. E. Hempson, who is retiring from the post of Solicitor to the British Medical Association after thirty years, gave clear advice in the course of an address at Hastings two years ago. He said:

"In my experience controversy frequently arises at the trial of an action as to whether the doctor did or did not recommend some particular form of treatment which the patient or the relative refused, and no conclusive evidence is forthcoming on the subject. It may be indeed the vital point upon which the whole allegation of neglect is based, and I can recall instances in which this has been the case. The position which I indicate must, I am sure, often occur in the practice of every medical man. My advice to you is that when it does happen note it in your books; such a note as this would suffice: 'X-ray treatment advised and refused.' In addition, take the simple precaution of placing it on record in a letter to your patient, and keep a copy of it. This may be the means of saving serious trouble in the future. I have in mind one case in particular which turned on this point—namely, 'Did or did not the doctor recommend that the injury which was obscure should be x-rayed?' The doctor affirmed that he did, and that he offered to take the patient to the radiologist then and there in his own car. The patient denied that any such suggestion was made by the doctor, stating that he, the patient himself, in fact, suggested it to the doctor, who said that there was no occasion for it being done. This case passed through two trials, at a cost of nearly £1,000, and had the precaution which I now advocate been taken I am convinced that it would never have been brought into court at all."

### STANDARDS OF SOBRIETY.

THE difficulty of the police courts in the absence of any authoritative legal definition of what constitutes drunkenness is illustrated almost every day. Not long ago Sir Robert Wallace, K.C., chairman of the London Sessions, having before him a taxi-driver charged with drunkenness while driving his vehicle, intimated that if the accused were found guilty he would grant leave to appeal with a view to eliciting from the Court of Criminal Appeal some direction upon which lower courts could proceed. Unfortunately for future jurisdiction—though fortunately enough for the accused person—Sir Robert Wallace, in his address to the jury, examined the case with such nicely balanced precision, omitting no point which could tell on either side, that the jury, without leaving the box, gave the accused the benefit of the doubt, and so the case never reached a higher court at all.<sup>1</sup>

More recently, at Marylebone police court, when a man was summoned for being drunk in charge of a motor car, for driving the car in a manner dangerous to the public, and for not having a driving licence, the divisional surgeon testified that the man was drunk "in view of his symptoms and of the history of the case," whereupon the magistrate (Mr. Hay Halkett) intervened: "I want to keep you away from that. You have nothing to do with motor cars or anything like that." The divisional surgeon then explained that in his view the defendant was in a condition where lapses of judgement and errors in direction and co-ordination were likely to occur, but he agreed that if the man had been walking in the street he would not have certified him as drunk. The magistrate remarked that the law did not require a higher degree of sobriety in persons in charge of motor cars than in persons walking in the street; he agreed that it might be a good thing to exact a higher standard, but it was not the law of the land. In the result, however, the magistrate fined the defendant a total of £14 on the three charges, which included the charge of drunkenness, and disqualified him from holding a licence for twelve months.

A certain inconsequence about the conviction, following the doctor's statement that if the man had been walking in the street he would not have formed the opinion that he was drunk, and the magistrate's statement that the law does not require a higher degree of sobriety among pedestrians than among motorists, may be due to the necessarily summarized character of the newspaper reports, and the magistrate may have had further evidence which convinced him of the defendant's drunkenness. But on the face of it, we think the divisional surgeon expressed the common sense of the situation, and also that, in spite of a deprecatory frown from the bench, he might properly have regarded as a medical man to the fact that the accused person was driving a motor car, and to the facilities which motor driving demands. There is bound to be in the public judgement a higher standard for motorists or any persons in charge of complicated machinery, in whom even a momentary aberration may have disastrous consequences, than for persons without the same access. The community might well tolerate on the part of a signalman off duty a manner of behaviour which it would visit with the severest condemnation if he were in his cabin, and this, we believe, is the principle adopted by railway companies. There are not only degrees in the state of drunkenness, but degrees also in culpability arising out of the circumstances in which the drunkard or the "person under the influence of drink" is placed. But there is a further consideration—that even for the pedestrian the offence of drunkenness cannot be regarded with anything like the former leniency, for the pedestrian who is the worse for liquor may easily be the cause of a serious accident. In fact, upon the whole community a higher standard of social behaviour is being imposed by the very complexity of modern civilization. New occasions not only teach new duties, but involve new restraints.

## The Services.

### ROYAL NAVY MEDICAL CLUB.

THE annual dinner of the Royal Navy Medical Club will take place this year at the Trocadero Restaurant, Piccadilly Circus, on Thursday, April 26th, at 7.30 for 8 p.m. Members who wish to be present are asked to inform the honorary secretary, Royal Navy Medical Club, Queen Anne's Chambers, Tothill Street, S.W.1, not later than seven clear days before that date.

### NAVAL MEDICAL COMPASSIONATE FUND.

A MEETING of the subscribers of the Naval Medical Compassionate Fund will be held at the Medical Department of the Navy, Queen Anne's Chambers, Tothill Street, Westminster, S.W.1, on April 26th, at 11.30 a.m., to elect six directors of the Fund.

<sup>1</sup> See *British Medical Journal*, February 18th, 1928, p. 283.

## Obituary.

## THE LATE SIR DAVID FERRIER.

WE have received from Sir CHARLES BALLANCE the following tribute, supplementing the memoir we published last week:

Sir David Ferrier belongs to that small group of great men who rediscovered and recreated the science of experimental neurology, lost to mankind since the times of Galen. Ferrier was experimenting before Charles Beever, Victor Horsley, or myself were students of medicine. His first paper was published in 1873. In this paper numerous experiments were related bearing on the subject of the localization of the functions of the brain. Some later papers dealt with the discovery of the visual and auditory centres, and the understanding of the symptom-hemianopia, and in 1879 two papers were published, (1) on pain in the head, and (2) on vomiting, in connexion with cerebral disease. The supreme value of the experimental method was exemplified in Ferrier's life and work. He was fond of quoting from G. H. Lewes, "Every discovery is a verified hypothesis; and there is no discovery until verification has been gained; up to this point it was a guess, which might have been erroneous." Cruveilhier, in 1830, knew, as Hippocrates did, that a lesion of one side of the brain was not seldom associated with paralysis of the opposite side of the body. Broca showed at the Anthropological Society of Paris in 1861 the brain of a man who for twenty-one years had lost the faculty of speech. There was softening of the third left frontal convolution. Fritsch and Hitzig, in 1870, marked out certain centres on the brain by means of electrical stimulation; but Ferrier soon left this work far behind by precisely charting on the cerebral cortex certain centres for movement and for the special senses. How little these facts and the inferences from Ferrier's paper in 1873 had reached the mind of the profession is illustrated by the statement made in a lecture I attended six years later, in 1879, as a student, that "the brain functioned as a whole."

Ferrier's work was brought prominently into notice in the Physiological Section of the International Medical Congress in 1881. A dog was shown by Goltz and two monkeys by Ferrier. Experimental injuries had been inflicted on the cerebral cortex of each of these animals. The condition of the dog was supposed to prove that localization of function in the cerebral cortex did not exist. One of the monkeys had characteristic cerebral hemiplegia; as it came into the room Charcot remarked, "It is a patient." The other monkey showed no signs of hearing when a percussion cap was snapped in its immediate vicinity. Thus all doubt as to the truth of the great doctrine of cerebral localization was laid to rest, and the ground was prepared for the marvellous progress of the coming years. Ferrier, in the Marshall Hall Oration in 1883, said that "Up to that time cerebral localization had been absorbed like latent heat by medical science itself as distinct from medical and surgical practice, but that the unflinching safety of experiments on animals made it clear that similar results would soon be achieved on man himself." This forecast was soon to be verified by the wonderful operations of neurological surgery.

While it is comparatively easy to trace in history Sir David Ferrier's share in the progress of neurology, it is more difficult to write of his attractive and vivid personality. To me the world seems barren without the presence of my great friend. Sir David was of slight build, his mind was extraordinarily alert and full of many kinds of knowledge, and his hands were small and capable of the most delicate manipulations. I often said to him that it was a good thing for some of us that he was not a surgeon. From the time that I was elected on the staff of the National Hospital, Queen Square, now nearly forty years ago, Sir David was in all circumstances and at all times a most inspiring and kind colleague. No wonder, then, that my memory of him is one of deep affection and admiration. No time or trouble was of any importance to him if he could, by his presence or counsel, aid me in

my work. Up to the time of his last fatal illness his mind was as keen and eager concerning problems in neurology as it was when I first knew him. Many, I am sure, could testify as I am trying to do.

Sir David was never so happy as when he was able to place his rare genius and wisdom at the disposal of, and for the encouragement of, a junior. His delightful keenness and intense interest when attending an operation or an experiment often masked to other visitors the real reason of his presence, which was to give support and confidence to a friend or junior. He has built in the minds of those privileged to be associated with him a temple of gratitude, and has left behind him a rich legacy—the example of a long life of unselfish scientific labour and a record of splendid and fruitful achievement.

In the gradual evolution of truth it would seem that at the end of each stage of the history of knowledge a great man appears who is the herald of the dawn of a wider insight into light and truth. Carlyle, in his lecture on the hero as poet, takes as examples Dante and Shakespeare; he calls them "the Saints of Poetry." Two great and fit men appeared in the sixties of the last century: Hughlings Jackson and David Ferrier. They may be named "the Saints of Neurology." Hughlings Jackson represented, as Hippocrates did, the highest development of intellectual and clinical research—the very soul of neurology; while David Ferrier, the "soul of practice," awoke in the minds of his contemporaries and later fellow workers a desire to explore the old ground by the experimental method, and to unearth truths long concealed. Every part of neurology has felt the vivifying influence of the principles and practice emanating from the bold imagination and inventive genius of these great men. The influence of their labours on the progress of the physiology and pathology of the nervous system has been universal and immense, and thus to them science owes an incalculable debt.

The world moves on in a succession of dreams and their fulfilment, and the wild imaginings of one age become the splendid realities of the next. We ought never to forget what is due to those who have gone before. It is difficult for anyone to bring himself to believe that what is now the easy and obvious property and knowledge of all was once the perilous and toilsome discovery of David Ferrier. As Hughlings Jackson is the Socrates of neurology, so Ferrier may be described as the John Hunter of neurology. It was the boast of Augustus that he found Rome built of brick, and left it built of marble. Jackson and Ferrier found the knowledge of cerebral physiology practically non-existent; they have left it a beautiful science. We speak of the immortal labours of Pasteur and of Lister; it is also true to speak in the domain of neurology of the immortal labours of Jackson and Ferrier. They are among the greatest benefactors of the human race. They have made straight the way for us, their humble surgical followers.

Dr. ALDREN TURNER sends us the following appreciation:

The death of Sir David Ferrier, after an illness of some duration, recalls to many a vivid personality in the profession of medicine and work of a pioneer character accomplished more than fifty years ago. In the seventies of the last century, and for many years afterwards, the name of Ferrier was associated with certain areas of the cortex of the brain, to which he had attached specific functions as a result of original and careful experimentation. This was the first precise effort in this country to elucidate the functions of the brain on scientific and experimental lines, and to clear up much which up to that time had been vague, theoretical, and speculative in this connexion. The results of his experiments were given in a number of papers in various scientific journals, but his most important work, *The Functions of the Brain*, was first published in 1876, and in it he presented a systematic exposition of the bearing of his experiments on cerebral function. Ten years later a much enlarged and almost entirely rewritten edition was published, and attracted universal attention, as it presented to the reader what were the established facts of physiological research into the functions of the

brain, as revealed by his own work in conjunction with that of his contemporaries. Much of his original work was published in the *Transactions* of the Royal Society, in *Brain*, and in numerous lectures, papers, addresses, and communications to learned societies during a number of years. As an example of his graphic method of demonstrating his work, reference may be made to the exhibition of a monkey at the International Medical Congress in London in 1881. Before exhibition he had destroyed the first temporo-sphenoidal convolution on both sides. While the animal was disporting itself in the presence of the assembled physiologists a percussion cap was exploded. The monkey remained perfectly unconcerned and gave not the slightest indication of having heard anything, while another monkey was observed to start suddenly and show signs of fear.

At an early age, in conjunction with his colleagues Jackson, Gowers, Bastian, and others, he became one of the founders of the British school of neurology, which has contributed so extensively and fruitfully during the last half-century to our knowledge of the structure and functions of the nervous system, and has done so much to promote the study of nervous diseases throughout the world. To his medical colleagues, and to a large public, he soon became known as one of the foremost of scientific physicians of his day, and he rapidly acquired an extensive consulting practice. He served upon the medical staffs of King's College Hospital and the National Hospital in Queen Square, holding successively the posts of assistant physician and physician, and eventually becoming consulting physician. In hospital and in private practice he possessed a manner and a style in the examination and treatment of a case which carried conviction. He was an investigator rather than a teacher, a physiologist perhaps more than a clinician. The bent of his mind in youth was towards philosophy and the classics, but he developed into a man of science, and later became a physician whose opinion in difficult cases was largely sought.

Sir David Ferrier's industry was enormous. Over a period of about thirty years his working day began at 8.30 in the morning and rarely terminated before midnight. When I became associated with him in experimental work in the neuro-pathological laboratory of King's College in 1890, although his days were fully occupied with hospital duties and the heavy burdens of an increasing practice, he found time to visit the laboratory most afternoons and to assist in experiments from time to time. One of the most remarkable features of his career was that throughout his professional life he combined the pursuit of science with the practice of his profession. His earliest experimental work dates from 1873, while his last contributions were published in 1898—a period of twenty-five years. He was essentially an enthusiast both in work and play. The former had no terrors for him, while into the latter he threw all the energy, interest, and spirit of an almost boyish nature. He was a man of action, forceful in purpose and tenacious of his opinions; yet withal a man of affectionate and kindly nature, and imbued with much human sympathy. His physical and mental make-up showed the character of the man. A short and spare figure, a strong nose and chin, and sharp features, combined with great alertness of mind and manner, and an inquiring disposition, denoted the energetic and successful seeker after information. He thought clearly, wrote clearly, and spoke clearly, his speech having a slight accent, denoting his Scottish origin.

He found rest, pleasure, and recreation upon the sea. At one period of his life his autumn holidays were devoted to deep-sea fishing off the Cornish coast, while in later life he took kindly to golf. To most men retirement affords an opportunity for ease and relaxation, but to Ferrier it was an occasion for gratifying his dominant interest in medical and scientific matters. He was a regular attendant at the College of Physicians, of which he had filled most of the offices, at the Royal Society, the Royal Institution, and the Royal Society of Medicine. During the last two years of impaired health he fought his disability as strenuously as he had fought the battles over cerebral localization in his earlier life.

Mr. WALTER G. SPENCER writes:

I would like to mention the first occasion and the last one on which I had the opportunity of listening to Sir David Ferrier. On the first, at the Brown Institution, Horsley and Beever were engaged in electrically exciting areas on the surface of the brain of an anaesthetized anthropoid ape. Ferrier was looking on, and discussing confirmations and minor elaborations of results obtained by him upon lower-grade monkeys, as well as the pathological correlations which had followed. Shortly before last Christmas I was able to show to Sir David Economo's *Atlas*, just purchased by the Royal Society of Medicine for its library. As we viewed each of the much-enlarged photographs of microscopical sections taken from the surface of the brain, each demonstrating some variation in one from the other, he took special delight in noting that a difference in structure was now demonstrable, confirming differences already proved to exist as the result of experimental and pathological inquiry. It was very evident that Sir David Ferrier not only retained his memory, but had kept up acquaintance with the progress of neurology.

#### GEORGE STEVENSON MIDDLETON, M.D., M.A., LL.D.,

Consulting Physician, Royal Infirmary, and Royal Hospital for Sick Children, Glasgow.

We have to announce with much regret the death of Dr. George Middleton, one of the leading figures in the medical profession of the West of Scotland, which took place at his residence in Glasgow on March 21st, after a painful and prolonged illness.

George Stevenson Middleton was born in Aberdeen in 1853, and received his early education at the Grammar School there, proceeding later to the University and graduating in arts with honours in 1873. Among his classmates there were Sir Watson Cheyne and Dr. Andrew Laws, the medical missionary. It was, however, in Glasgow that he commenced his professional studies, graduating M.B., C.M. in 1876, and proceeding to the degree of M.D. in 1884, on each occasion with honours. In 1893 he obtained the diploma F.R.F.P.S.Glas.

After graduating Dr. Middleton held resident posts successively at the Royal and Western Infirmaries in Glasgow, being associated there with the work of Sir Hector Cameron and Sir William T. Gairdner. Later he accepted an appointment as superintendent of Knightswood Fever Hospital, but work of this kind did not possess much attraction for him, and before long he resumed his connexion with the University on becoming assistant to his former teacher, Professor Gairdner, a position which he held for thirteen years. In 1894 he was appointed full physician at the Glasgow Royal Infirmary, with which he was actively associated for nearly twenty years. His success as a teacher during this period may be judged from the fact that his former students deemed it worth while to induce him to conduct for their benefit a special class, which may be regarded as constituting the foundation of post-graduation work in Glasgow. From 1906 for several years he gave his services also as senior physician to the Royal Hospital for Sick Children, Glasgow, holding office as honorary consulting physician to that institution and to the Royal Infirmary after his retirement. During the war he held a commission as lieutenant-colonel, R.A.M.C., and was chief physician to the 4th Scottish General Hospital, Stobhill, Glasgow.

Dr. Middleton took a full share in public affairs, devoting himself largely, as was natural, to higher education. For eighteen years he was a member of the board of the Royal Technical College, Glasgow, and in 1918 he was elected to the council of the University of Glasgow, which, in 1915, had conferred on him the honorary degree of LL.D. He represented the Royal Faculty of Physicians and Surgeons on the board of governors of the Royal Samaritan Hospital for over a quarter of a century. In both the Association of Physicians of Great Britain and Ireland and in the Glasgow Medico-Chirurgical Society he had held office as president. His decision to retire from active practice was announced just over two years ago,

when, at a gathering described as unique in the medical history of Glasgow, he was entertained to dinner on the occasion of his seventy-third birthday by an assembly of his old college friends, colleagues, and assistants.

We are indebted to Dr. C. O. HAWTHORNE for the following personal appreciation:

Although Middleton held for many years a prominent position as a physician and clinical teacher in the medical school of Glasgow it was neither his professional status nor his recorded work that explained the influence he exerted on his colleagues and the regard he received from them. For long, neither himself nor his work gained much in the way of recognition. He had no gift of self-assertion, and his temperament led him to quiet studies rather than to controversial activities or to brilliant achievements. Ready methods to popular success were not for him, and his limited ability to see a virtue in compromise did not always commend him to his colleagues. He was not conciliatory when he felt a principle to be at stake, and he was inclined strongly, and even obstinately, to hold to his own views; while, if he had prejudices, he did not disguise them. Altogether, partly from circumstances, partly from his personal qualities, the earlier part of his professional life was hardly an easy one or an encouraging one.

The later part of the story is of happier quality, for it includes confidence freely given and fully justified, work worthily accomplished, merit recognized, and "honour, love, obedience, troops of friends." And the contrast between the earlier and the later years finds its explanation in the character and personal qualities of the man as these gradually became manifest in professional work and responsibilities, and in the opportunities of social life and comradeship. Efficiency and thoroughness and sincerity were the conspicuous notes of his practice as a clinical teacher and physician, and many of his pupils and house-physicians became not only his disciples, but also his devoted admirers and affectionate friends. Gradually his capacity for sound and impartial judgement and his unbending rectitude won the confidence of his colleagues, and thus high duties were entrusted to him without hesitation. Everyone recognized, whether in agreement or in disagreement, that he was ever loyal to what he conceived to be the worthy motive and the larger interest. His decisions and opinions might be questioned, but never his integrity. In personal friendships, as in public affairs, he knew the meaning of loyalty and sincerity and frankness. No master of smooth phrases, he never shirked a candid judgement, and his counsel, often sought, was valued even when it was unpalatable. To the new generation Middleton was necessarily the representative of the older school and the established tradition, but those of us who knew him well through many chequered years will recall him as one who, "in praise and in dispraise the same," held ever a steady course and gave of his best to the cause and service of professional duty and of loyal comradeship.

#### RICHARD JOHN KINKEAD, M.D.,

Professor of Obstetrics and Gynaecology, University College, Galway.

We regret to announce the death of Dr. Richard John Kinkead, for fifty-three years professor of obstetrics and gynaecology at University College, Galway, which took place at his residence there on March 18th, at the age of 84.

The son of a clergyman, he was born at Ballina, county Mayo, in 1847. He received his medical education at the schools of the Royal College of Surgeons of Ireland and Trinity College, Dublin, obtaining the diplomas L.R.C.S.I. and L.M. in 1865 at the age of 19, and graduating M.D. (Dubl.) in 1873. For a brief period, between 1865 and 1867, he practised in Tuam. In 1875 he was appointed professor of obstetrics and gynaecology at Queen's (now University) College, Galway, and held that appointment to the time of his death, being also lecturer in medical jurisprudence and hygiene. He acted as examiner in these four subjects to the National University of Ireland. For nearly fifty years he was gynaecologist at the County Infirmary, now merged in the Central County Hospital, Galway, and for an almost equally long period, covering

the troubled times of the earlier Home Rule agitation, the Sinn Féin disturbances of the pre-treaty years, and the later civil conflict, he was medical officer at Galway Prison. Dr. Kinkead was a Fellow of the Royal Academy of Medicine of Ireland, and had held the office of president of the Irish Medical Association. He was the author of a number of publications, of which the titles are a sufficient index to his versatility; they included *Our Homes*, *The Irish Medical Practitioners' Guide*, *Insanity*, *Inebriety and Crime*, and *Our Senses and How They Serve Us*.

The affairs of the College to which he was attached attracted a large share of his attention, apart from his teaching work. He was a member of the council of the old Queen's College and of the governing body of its successor, one of the constituent units of the National University of Ireland, until recently, and as auditor of Queen's College gained fame as a public speaker. He had for some time past been unable to fulfil his professional duties, but the governing body of the College decided, in recognition of his work, to retain his services.

In the Church of Ireland he ranked among the leading personalities in the diocese of Tuam throughout his life, and a few years ago his services were recognized by a presentation from the bishop, clergy, and laity. He was a member of the General Synod of the Church, and lay honorary secretary of the Tuam Diocesan Synod; and in his own parish of St. Nicholas had occupied almost every office open to a layman. As a Freemason he held the position of Provincial Grand Master for South Connaught.

A colleague, "J. M.," writes: A man of remarkable force of character and originality has passed away in the person of R. J. Kinkead, who has been for several generations of medical students one of the outstanding figures of University College, Galway, which, although one of the smallest and poorest of the university centres of Great Britain or Ireland, has a far-flung chain of alumni wherever English is spoken. In the training and education of these men to adapt themselves so well to all circumstances Kinkead took a large part. He was a fearless operator and never failed to command the interest of his class in the lecture room and the wards. His interest in professional affairs was unflagging, and many years ago he was elected by his professional brethren, president of the Irish Medical Association. A phase of his work which brought him into the limelight which illumines the ephemeral political celebrities and those in contact with them in a country given to political activity, was his position as surgeon to the county gaol, which was frequently in former troubled days selected for the concentration of a number of political prisoners. In a very difficult position Kinkead ran his course so fairly and evenly that no party had any opportunity to attack him. Among those who came under his care were the late Mr. John Dillon and the late Mr. William O'Brien. In addition to his professional activities he took a large part in the life of the community. With his outspoken honesty, robust common sense, wide sympathy with his fellows, and large outlook on life he filled a place in the regard and esteem of his contemporaries not often attained, and I think this short and inadequate tribute will find an echo wherever the past students of Galway College are to be found.

#### JOHN PERCY INGHAM HARTY, F.R.C.S. Eng., B.A., M.B., B.Ch. R.U.I.,

Surgeon, Ear, Nose, and Throat Department, Bristol Royal Infirmary.

We regret to announce the death, at the early age of 47, of Mr. John Percy Ingham Harty, honorary surgeon to the ear, nose, and throat department of Bristol General Hospital, who died on March 10th after an operation for duodenal ulcer.

Mr. Harty received his early medical education at Queen's College, Cork, and in 1902 graduated M.B., B.Ch., B.A.O. R.U.I. After spending several years in private practice at Halifax, he decided to specialize in nose and throat work, and studied in Leeds and London. In the short period of eighteen months he passed both the primary and final examinations, and in 1912 obtained the diploma

F.R.C.S. Eng. After holding resident appointments in London and Cardiff, he went to Bristol as house-surgeon to the ear, nose, and throat department of the Royal Infirmary, subsequently becoming registrar of the department, and beginning private consultative work with immediate success.

Mr. Harty was a keen Territorial officer, and on the outbreak of the late war was mobilized with the 3rd South Midland Field Ambulance. He accompanied that unit to France early in 1915, but soon afterwards was attached to the 6th General Hospital at Rouen as a specialist, and organized the nose and throat department for the Rouen base. While holding this appointment the illness first developed which ultimately caused his death. Towards the end of the war he was transferred to the Royal Air Force, and served with it as a specialist until his demobilization in 1919. On returning to Bristol he resumed his work, and in 1921 was appointed honorary surgeon in charge of the ear, nose, and throat department of the Royal Infirmary. He held a number of other public appointments in Bristol, being clinical lecturer on laryngology to the University, consulting surgeon for diseases of the ear, nose, and throat to Southmead Hospital, and aural surgeon to the Education Committee. He was a member of the British Medical Association and of the Bristol Medico-Chirurgical Society.

A colleague writes: The death of J. P. I. Harty has deprived Bristol of one of its best known consultants, and has caused a gap in the circle of his colleagues and friends which it will be well-nigh impossible to fill. Those who met him for the first time after the war little realized how much it had changed him. A noted Rugby player (he played twice for the South of Ireland, and was "capped" for his medical school all the time he was a student), he played most games well, and was endowed with a magnificent physique. A typical cheery Irishman, with a never-ending fund of good stories and jokes, he was the best of companions, beloved alike by his colleagues and patients. From the date of his first illness in France he never enjoyed good health, and in later years, in spite of numerous operations, he was greatly aged and never free from pain—at times very severe—but always so bravely borne that those who did not know him well seldom had any idea of the distress he was enduring. He "did great good by stealth." The shoals of letters received from his poorer patients are an eloquent testimony to the affection he inspired in them. He married, in 1916, Helen Dorothy, daughter of the late Dr. Clarke of Kensington, and leaves two young sons.

#### JAMES DAVISON, M.D., M.S., M.R.C.P.,

Consulting Physician, Royal Victoria Hospital, Bournemouth.

It is with much regret that we have to announce the death of Dr. James Davison of Bournemouth, who died there on March 18th, in his eighty-second year, as the result of an attack of pneumonia supervening on an illness which had kept him confined to his bedroom for several months.

He was a native of county Down, and commenced his medical education at Queen's College, Belfast, proceeding later to Dublin, and graduating M.D. in the Queen's University of Ireland in 1869, and M.S. ten years later. He afterwards pursued his studies in Edinburgh and London, and in 1889 he obtained the diploma M.R.C.P. Lond. For a short time after beginning his professional career he practised in Sheffield, where he was demonstrator in anatomy in the Sheffield Medical School, and afterwards he visited South Africa and New Zealand. On returning to England he settled down in Bournemouth, commencing in 1882 the association with that place which continued until his death. There Dr. Davison soon established an extensive family practice, although in later years he specialized in diseases of the ear, nose, and throat. He was among those largely responsible for the establishment and organization of the Royal Victoria Hospital, Bournemouth, which was opened in 1891. For a period he served on the staff as senior physician and physician in charge of the ear, nose, and throat department, and he was latterly consulting physician to the hospital. In 1888 he was elected physician

to the Royal National Sanatorium for Consumption and Chest Diseases, Bournemouth, being consulting physician at the time of his death. He was also honorary examining physician to the Alexandra Sanatorium, Davos, Switzerland.

Dr. Davison, throughout his active life, took a considerable part in professional affairs, and over a long period filled various offices in the British Medical Association, being a member of Council in 1910. The period of his service as honorary secretary of the Dorset and West Hants Branch included the year 1891, when the Annual Meeting of the Association was held at Bournemouth; as local secretary his ungrudging expenditure of time and money did much to make the meeting a success. In the Dorset Branch he was a member of the council for several periods, acted as secretary for a second term, and held office as president in 1886. At the Annual Meeting of the Association in 1892 he was vice-president of the Section of Diseases of Children. Only last year, in making a routine communication to the Central Office, Dr. Davison took occasion to express his continued interest in the advancement of the Association's work and to voice his regret at being unable to see the new premises. He was also a Fellow of the Royal Society of Medicine and of the Medical Society of London, and had been president of the Bournemouth Medical Society and vice-president of the British Laryngological, Rhinological, and Otolological Society.

His favourite recreation most of his life was horseriding, and in his earlier years he was a keen follower of hounds, riding regularly with Lord Portman's and the New Forest packs, and it was with regret that he was forced, with the passage of time, to abandon this pastime. While he did not take any very prominent part in public affairs, other than those associated with his profession, he was a well-known and popular figure in Bournemouth.

At the funeral at St. James's Church, Pokesdown, representatives were present from the Dorset and West Hants Branch of the British Medical Association, the Bournemouth Medical Society, and the staffs of the Royal National Sanatorium and of the Royal Victoria and West Hants Hospital. Dr. Davison is survived by his widow and two daughters.

#### HENRY GOFF KILNER, M.B., B.S.,

Honorary Surgeon to the West Suffolk General Hospital.

By the sudden death, on March 17th, of Dr. H. G. Kilner, at the age of 42, East Anglia has lost one of its most greatly loved and talented sons. The second son of Dr. Charles Scott Kilner, Henry Goff Kilner was the fourth generation of that family to practise medicine in Bury St. Edmunds. Educated at King Edward VI's School in Bury, he entered the Middlesex Hospital, where, after a brilliant career in the medical school, he gained the senior Brodrip Scholarship. After qualifying as M.R.C.S., L.R.C.P. in 1909, he held the appointments of house-physician, house-surgeon, and obstetric house-physician, and became demonstrator in anatomy. He graduated M.B., B.S. Lond. in 1912, and was appointed house-surgeon at St. Peter's Hospital for Stone. On the outbreak of war Kilner was gazetted second lieutenant to the 5th Suffolks, and served as a combatant till the Army Order of the summer of 1915 requisitioned medically qualified men to associate themselves with the R.A.M.C. He was present at Gallipoli, where he served in a hospital ship. Subsequently he was on the headquarter staff at Mudros, and then in Egypt with the 29th Division. At a later date he served with the 7th Field Ambulance in France, and became D.A.D.M.S. to the 2nd Cavalry Division. While there he was awarded the Croix de Guerre and was twice mentioned in dispatches.

Returning to Bury St. Edmunds after the war, Kilner acted as surgeon to the hospital for disabled men under the British Red Cross Society and the Ministry of Pensions, and was elected honorary surgeon and honorary radiologist to the West Suffolk General Hospital. He was a loyal worker in the British Medical Association. He served on the Suffolk Branch Council in 1920-22, was the representative of the West Suffolk Division in the Representative Body in 1920-21, and was a member of the Executive Committee of the Division in

1923. In 1916 he had married Olive Simpson, the daughter of the late R. T. Simpson and Mrs. Simpson of Horsecroft. His widow is left with two young children, aged 7 and 4, to mourn their loss.

"C. E. L." writes: Kilner was a humanist to the core, and he could never spare himself where he felt that anyone was in need of him. His kindness was unbounded, and it is many a lame dog he has helped over a stile. The hundreds that thronged the churchyard bore eloquent testimony to the love and respect of numberless patients whom he had benefited. He was the most loyal of friends and the best of companions, and over all there was that abiding cheerfulness and inexplicable charm which comes not from the head, but from the heart. The wind, the sun, and the open country were as the breath of life to him. He was a keen naturalist and an archaeologist of no mean order. He was perhaps most happy tramping over his native soil in search of some rare bird or on his way to show a friend one of the many architectural glories with which his countryside abounds. He loved life, and his spirit of enjoyment was infectious. *Vale, vale, dilectissime!*

Another colleague writes: Kilner was an exceptional man. In addition to bearing the brunt of a busy practice he did an immense amount of work at the West Suffolk General Hospital which was invaluable. Nothing but a boundless energy and complete unselfishness could have enabled him to cover the ground he did. He was a first-class general surgeon, and owing to his training at St. Peter's had a special knowledge of genito-urinary work. Few men would have had the energy to undertake any more for the hospital; yet Kilner took over the x-ray department almost in its infancy, and worked it up to a state of efficiency of which the hospital is justly proud. He also assisted the consulting orthopaedic surgeon, and was in charge of the department between his visits. Whatever the pressure of work, no one ever appealed to Goff Kilner for help in vain, and his death leaves a deep sense of personal loss which is felt by all his colleagues in West Suffolk.

#### LIONEL R. FIFIELD, F.R.C.S.,

Surgical First Assistant, London Hospital.

THE tragic death in a street accident of Mr. Lionel Richard Fifield on March 21st, at the age of 30, has removed a most promising surgeon. He received his medical education at the London Hospital, where he obtained the diplomas M.R.C.S., L.R.C.P. in 1921, and the F.R.C.S. Eng. in 1923. Previously to this he had enlisted as a combatant in the war, and served in France, where he was wounded, and received a commission. He held various resident appointments at the London Hospital, including that of house-surgeon to the surgical teaching unit under Mr. H. S. Souttar; for some years he was demonstrator of anatomy, and in 1925 he was appointed surgical first assistant. As an operator Fifield was quick and careful, and his judgement was always to be depended on; his clear reasoning and power of lucid explanation rendered him very popular as a teacher. He was highly esteemed in the Law Courts as a reliable witness and a surgeon equipped with sound knowledge and skill in presenting the facts of a case and the inferences to be drawn from them. His publications included *Minor Surgery*, which was reviewed in our columns on November 7th, 1925 (p. 850), and *Infections of the Hand*, which was noticed on August 6th, 1927 (p. 218). He recently obtained the Buckston Browne prize of the Harveian Society for an essay on new growths of the bladder, which is to be published in book form. A colleague writes: Brilliant though he was, and recognized by all who knew him as a man of great ability and promise, he will be remembered even more, perhaps, for his kindly generous nature, unassuming modesty, genial humour, and unfailing sympathy. A man of keen ambition and indomitable energy, he was the soul of honour and incapable of any petty meanness or doubtful jockeying which might procure him advancement. A large gathering of the London Hospital staff, residents, and students attended the funeral ceremony; their numbers bore eloquent testimony to the affection and esteem in which their friend and colleague was held.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons this week had a second reading debate on the Equal Franchise Bill introduced by the Home Secretary. On the Consolidated Fund Bill discussions arose on the state of the populations in distressed mining areas and on the wisdom of placing the three fighting services under a central control. Several medical members were prepared to speak but could not, as the debate was curtailed for other business.

Objection was taken to the second reading of the Edinburgh Corporation Bill on March 23rd, and it was set down again for March 30th. The Edinburgh Corporation and the members representing the city are anxious that time should be provided for a discussion of its proposals for the control of venereal disease.

The House of Commons will adjourn for the Easter recess on April 5th and reassemble on April 17th.

### Bills.

On March 21st a bill to regulate the methods of slaughtering animals was presented by Mr. Noel Buxton, supported by Dr. Drummond Shiels.

On March 20th Miss WILKINSON introduced a bill to regulate offices and the employment of young persons therein. She said it sought to extend to people who worked in offices some of the protection at present given to those who worked in factories. The conditions in many big cities were rapidly growing worse, and something ought to be done to protect the health of the men and women who worked in offices. Many employees had to work under artificial light all day and every day, right through the summer, not only in old but in new buildings. In one of the best and newest offices in the City of London large provision was made for underground office accommodation. Damp was another enemy in these basement offices. She had brought to her notice the case of an office where girl clerks worked in the basement while books were stored in the sub-basement. The occupier found that his records and papers were mildewed, so he exchanged the places of the girls and the books. When she interviewed him this occupier said he could get no other office in which the girls could work. The effect of such conditions was worse because many of these girls worked long hours and special overtime at quarter-days. In some cases the electric light had a bad effect on the eyes. One-third of the disease among those who worked in offices was due to phthisis, and 122 out of every 1,000 died by diseases caused by working in cramped spaces with bad light, bad ventilation, and long hours. Many employers would welcome some legislation, and long hours. The bill made provision for adequate ventilation, latrine action. The bill made provision for proper sanitary accommodation, lighting, and heating, and for proper sanitary accommodation. It threw the burden of keeping offices in a proper condition on the owner. It would prevent overcrowding and would prevent any premises being used as underground offices which were not so used when the bill became law. The bill, which was supported by Dr. Drummond Shiels, was read a first time without a division.

### Invaliding from the Navy.

In the report stage of the Navy Estimates, on March 22nd, Sir GERALD HONLER returned to the question of invaliding out of the navy. He said he was not satisfied that, in deciding whether a man's invaliding was attributable to or aggravated by service, the Appellate Board had sufficient evidence concerning the state of the man might wish to make. There was some defect in the system. He cited the case of a man who got dysentery in the Red Sea, was sent to Malta, ordered home, recalled to the Red Sea, and became a constant invalid without an invaliding pension. Rear-Admiral BEANSMITH said he could not return too often to the question of tuberculosis and the invaliding of men. Invaliding was made upon secret and confidential instructions received from the Admiralty from the Treasury. He did not know whether there was any method by which the House of Commons could get hold of these instructions and see them. The rate of tuberculosis had been higher in the navy for at least four of the last five years than it had been in the army, and conditions of life in the navy were largely responsible for that difference. He urged that some change should be made, not only in the methods of invaliding men, but in the composition of the boards which invalidated them, and in the recognition of attributability in diseases and injuries for which the men were invalidated. Mr. KELLER said that very little regard was paid to the living conditions of the men of the lower deck on board ship, and modification of the men of the lower deck on board ship, and that so many of them were troubled with tuberculosis and other diseases. Dr. VERNON DAVIES said tuberculosis was a most serious subject, and he desired to arouse in the navy so that the Admiralty would feel compelled to do something. At present only 3 to 5 per cent. of the cases were held to be attributable. Men who went into the navy passed a medical examination so difficult that only 10 per cent. of recruits succeeded in passing the tests. They went in for five or ten, or fifteen years, then developed tuberculosis, were invalidated, and the Government and medical authorities said the disease was "not attributable." They could not wonder that men who went into the service physically fit, in the prime of their youth and came out practically condemned to death must hold the service had something to do with it. The different incidence of tuberculosis in the army and navy was not surprising in view

Mr. BALDWIN said that the present was a period of transition, and a continuation of the present methods met our peculiar conditions best. He would like to show, by way of illustration, what was being done by co-operation between the hospitals at the present time. In that respect there had been a move forward in the last year or two. The Royal Air Force had moved from the hospital at home, except the two big hospitals at Aldershot and Granwell. They had no hospital at Aldershot, but there was a small officers' hospital of twenty-five beds at Uxbridge for dealing with flying accidents which might occur at that centre. But abroad, where the Royal Air Force was in control, they maintained their own hospitals, and during 1925 there were up to 3,000 admissions of personnel of the navy, the British and Indian armies, and local forces of Iraq and Palestine treated in the Royal

Air Force hospitals. The military hospitals at Cosham and Devonport were closed in that year, and arrangements were made for the sick of the Portsmouth military area and of the military stations in the Devonport area to be treated in the Royal Victoria Hospital at Netley or the Royal Naval Hospital at Haslar; and the Royal Naval Hospital at Plymouth. No fewer than 3,000 of the R.A.F. personnel received treatment in the naval, army, and civilian hospitals during the last eighteen months. In the same way there had been considerable treatment of Air Force and army patients in the naval hospitals, both at home and abroad.

The possible pooling of other hospital arrangements had been examined, and in some cases had been found impracticable, but there were some places which were still under investigation. The Air Force itself made no general contracts in regard to medical supplies; it took the existing army contracts. Standardization and pooling had been agreed to in principle in regard to the ambulance trains, and the details were being worked out. The India Office was being invited to co-operate, and a number of other matters were now being studied by the general medical services, etc. In research co-ordination was effected through three co-ordinating boards for chemistry, physics, and engineering.

#### *Destruction of Vermin.*

In the House of Lords, on March 27th, Lord STRATHSPEY moved the second reading of the Public Health (Destruction of Vermin) Bill. He explained that the bill provided that if it appeared to the local authority, on the certificate of the medical officer or sanitary inspector, that any articles in any premises used for human habitation were infested with vermin, or were likely to be so infested, the local authority, at its expense, should cause those articles to be cleansed, disinfected, or destroyed. If it appeared to the local authority, on the certificate of the medical officer or the sanitary inspector, that any premises used for human habitation were infested with vermin the local authority should give written notice to the occupier or the owner if the premises were vacant, requiring him to cleanse the premises. The notice might require the removal of wallpaper or other covering from the walls. As a penalty for default a fine not exceeding £5 was provided, and a daily penalty of 10s., and the local authority was authorized to do the work and to recover the costs. Clause 3 provided that on the application of any person the local authority might take such measures as were deemed necessary to free that person and his clothing from vermin. Where it appeared to the local authority, on a report from the medical officer, that any person or his clothing was infested with vermin, and that person consented to be removed to a cleansing station, the local authority might cause him to be so removed. If he did not consent a petty sessions court, if satisfied on the application of the local authority that it was necessary, could make an order for his removal to the cleansing station. It was provided that the cleansing of females should be effected only by a registered medical practitioner or by a woman duly authorized by the medical officer. As soon as the occupier of a house became aware that it was infested he was required to send notice to the medical officer of health, and if a person became infested he must notify the medical officer.

LORD BANBURY moved the rejection of the bill, and said it was absolutely unnecessary. It enacted clauses already in existence, and some of the new clauses converted the private individual into a police officer. They would compel him to do the business of the local authorities, who already had powers through their medical officers and sanitary inspectors to find out if people had got vermin on them or not. Viscount GAGE said that the Minister of Health was not convinced that any real defect existed in the present law on these matters. After further discussion Lord BANBURY'S motion was carried without a division, and the bill was rejected.

*Diphtheria among Elementary School Children.*—MR. OTTO NICHOLSON asked, on March 22nd, whether parents of children attending elementary schools in the county of London were notified of cases of diphtheria in such schools, and given an opportunity of isolating any child who had been attending; and whether there was disinfection of classrooms in which cases had occurred. Lord EUSTACE PERCY said the arrangements made by the London County Council for dealing with cases of diphtheria in ordinary schools were based on experience over twenty years, and he was advised that all reasonable precautions were taken. He did not propose to interfere.

*Health of Workers in Artificial Silk Factories.*—MR. KELLY asked Sir W. JOYNSON-HICKS, on March 22nd, whether any of the reports received from Lancashire or Derbyshire on artificial silk factories showed that work in them was harmful to health. Sir W. JOYNSON-HICKS said the reports did not show this. Complaints about the Derbyshire works had been received in 1925 and 1926, but extensive alterations had since been made in plant and buildings, and no further complaints had been received. Mr. KELLY asked whether any recent reports had mentioned blindness due to working in the artificial silk industry. The HOME SECRETARY replied that no complaints had been received for a considerable time, and urged that if Mr. Kelly had information showing that blindness had arisen from working in the industry he should furnish the information to the Home Office. Sir WILLIAM added that he was unaware that any recent report from a Home Office inspector had mentioned any cases of eyesight being affected or of workers being operated upon for blindness. Artificial silk was a new industry. Home Office inspectors were watching it carefully, but at present had no evidence to establish it as being dangerous in any particular.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

DR. W. W. JAMESON, medical officer of health for Horsey and lecturer on public health and preventive medicine at Guy's Hospital Medical School, has been appointed, as from January 1st, 1929, to the University Chair of Public Health at the London School of Hygiene and Tropical Medicine.

The degree of D.Sc. in Anatomy has been conferred upon Professor W. E. Lo Gros Clark, F.R.C.S.

The Committee of the Medical Members of the Senate has appointed Dr. John Fawcett as its chairman for the remainder of the academic year.

### UNIVERSITY OF LIVERPOOL.

THE following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B.—Part I: J. D. Bright-Richards, J. P. Flanagan. Part II: A. L. Beresford, A. E. Carroll, A. Gardner, W. W. Gerrard, G. A. Talwin-Jones.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—N. J. Barton, R. V. Berrington, E. O. Fox, Norah M. Walker.

DIPLOMA IN TROPICAL HYGIENE.—R. R. Evans, W. J. Laird, H. V. R. Miller, G. H. Pearson, J. H. Pottinger, S. A. Wilkinson.

### VICTORIA UNIVERSITY OF MANCHESTER.

THE following candidates have been approved at the examination indicated:

D.P.H.—W. C. V. Brothwood, Miriam Florentin, T. Peirson, J. B. Wiley. DIPLOMA IN PSYCHOLOGICAL MEDICINE, PART I.—R. Handley, J. E. Howie, W. H. Shepley, H. Stafford.

The following awards have been made: Sidney Reusshaw Prize in Physiology, E. Davis; Danutsey Senior Medical Scholarship, R. V. Wright; Danutsey Junior Medical Scholarships, C. H. Gray, Philip Zimmermann.

### UNIVERSITY OF DUBLIN.

#### TRINITY COLLEGE, DUBLIN.

IN addition to those whose names were published last week (p. 529) receiving the degrees of M.B., B.Ch., B.A.O., the following have been approved at the examinations indicated:

FINAL M.B., PART I.—*Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene; Pathology and Bacteriology.*—A. G. Thompson, Lilla M. Spiller, T. E. McMahon, C. M. Taylor, M. E. Kirwan, R. P. M. Garrido, E. B. Lee-Wilson, F. O. W. A. Mahon. PART II.—*Medicine.*—D. S. P. H. Dundon, H. R. F. Treedy, R. F. W. K. Allen, A. J. Bur, J. Sayers, K. Watson, E. K. Malone, C. M. O'Brien, M. E. G. P. Martin, F. R. Falkner, I. W. Pigott, C. King, J. P. McGinn, R. M. Wilson, J. F. K. MacCarthy-Morrogh, J. E. McMahon, H. S. North, R. H. Bland, Mollie Finegan, J. A. Dowds, A. J. Burden. \* Passed on high marks.

### SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in the subjects indicated:

SURGERY.—P. O. Basu, M. Hurwitz. MEDICINE.—E. E. Bowen, K. J. M. Graham, H. J. Harcourt, M. Hurwitz, J. Beckitt, E. E. Bowen, M. Hurwitz. FOR . . . J. C. F. White, W. Ziv. K. McCoan, L. W. Sanders, W. Ziv.

MDWIFERY.—M. . . The diploma of the Society has been granted to Messrs. E. E. Bowen, H. J. Harcourt, and N. S. J. Roberts.

## Medical News.

SIR HUMPHRY ROLLESTON, on the occasion of his visit to Philadelphia to take part in the Harvey Tercentenary celebrations there, has been made an Honorary Doctor of Laws of Jefferson Medical College.

THE PRINCE OF WALES, as President of King Edward's Hospital Fund for London, has appointed Mr. Eardley Holland, M.D., F.R.C.S., F.R.C.P., to be a member of the Distribution Committee in place of Sir Francis Champneys, Bt., M.D., F.R.C.P., who has retired from the committee after eighteen years' service.

A CONJOINT meeting of medical practitioners and pharmacists will be held under the auspices of the South-East Metropolitan Branch of the Pharmaceutical Society, with the co-operation of the neighbouring Divisions of the British Medical Association, on Thursday, April 19th, at the Borough Medical Association, on Thursday, April 19th, at 3 p.m. Dr. E. G. Anais, Hall, Royal Hill, Greenwich, will take the chair, medical officer of health for Greenwich, will take the chair, and Dr. J. Stanley White will deliver a lecture, illustrated by films and slides, on some recent aspects of biological therapy.

At a meeting of the Royal Sanitary Institute to be held in the Sessions House, Maidstone, on Friday, April 13th, a discussion on the health of hop pickers and the sanitation of hop pickers' encampments will be opened by Dr. Alfred Greenwood, medical officer of health for Kent. The chair will be taken at 5 p.m. by Professor A. Bostock Hill. On the following day visits will be made to hop pickers' encampments and hospitals.

THE second lecture of the post-graduate course on cancer at the Leeds Medical School will be given on April 4th by Professor G. E. Gask on radium in the treatment of malignant disease. The first of these lectures was given by Sir Berkeley Moynihan on March 7th, and the final one will be delivered on May 9th, when Professor G. Grey Turner will discuss cancer of the rectum. The lectures are free to medical practitioners, who should, however, inform the secretary of the British Empire Cancer Campaign, 47, Park Square, Leeds, or their intended presence at least two days before the lecture.

A SERIES of six clinical demonstrations of types of mental disease, illustrated by numerous cases, will be given at the Maudsley Hospital Medical School, Denmark Hill, S.E.5, by Dr. Edward Mapother, medical superintendent, on successive Wednesdays, commencing on April 25th, at 2.30 p.m. The fee for the series, payable at the hospital, is one guinea. The first demonstration will deal with congenital and early types and with conditions associated with endocrine disorders; the second will cover psychoses associated with epilepsy and with syphilis, and the third psychoses associated with senility, with arterio-sclerosis, and with certain organic diseases of the brain. Alcoholic psychoses and dementia praecox will be the subjects of the fourth demonstration, and delusional states of the fifth; while the sixth and last, on May 30th, will be concerned with states of exaltation and depression.

WE gave an outline last week (p. 510) of the provisional programme for the Conference on Rheumatic Diseases to be held at Bath on May 10th and 11th. It will be followed on Saturday, May 12th, by the annual meeting of the Balneological Section of the Royal Society of Medicine. There will be demonstrations of treatment on appropriate cases at the hot mineral baths at 9.30 to 11 a.m., and of clinical cases at the Royal Mineral Water Hospital from 11 a.m. to 12.15 p.m. Those taking part in the Conference on Rheumatic Diseases are cordially invited to attend these demonstrations.

THE first general meeting of the Wolverhampton and District Clinical Club was held in the board room of the General Hospital on March 20th, with Dr. S. C. Dyke in the chair. Discussion centred on the constitution, which is designed to give members of the club an opportunity for exchanging experiences and opinions in an informal way. A programme of meetings has been arranged. The next meeting will be held at the General Hospital on Tuesday, April 17th, at 8.30 p.m. The honorary secretary is Dr. R. L. Mackay, Woodfield Avenue, Wolverhampton.

THE Board of Education announces that its Medical Branch will be transferred from 54, Victoria Street, S.W.1, to Whitehall, on April 2nd. Correspondence from that date should be addressed to the Secretary, Board of Education (Medical Branch), Whitehall, S.W.1.

THE Standing Committee appointed by the Board of Trade heard evidence on March 19th and 20th in connexion with an application for an order that imported instruments used in the medical, dental, and veterinary professions, dental supplies, and dental furniture should bear an indication of origin. The inquiry was closed, and the report of the committee will in due course be made to the responsible Minister. In the application, the Surgical Instrument Manufacturers' Association and the Association of Dental Manufacturers and Traders of the United Kingdom were supported by the Sheffield Surgical Instrument Makers' Association, opposition being offered by a group of dealers and importers. It was stated on behalf of the applicants that they desired to ensure that there was no chance of their products being confused with inferior foreign-made goods, and it was alleged that in some cases imported instruments were stamped as British after being received in this country. Another statement suggested that the Germans did not mark their inferior products, but stamped their best articles "Made in Germany." A witness for the opposition said marking would cause great trouble. Purchasers were usually more interested in the quality than in the origin of goods, while hospitals bought British or foreign supplies according to the funds at their disposal.

THE Guide to the British spas and climatic health resorts, which is published as part of the *Medical Directory* for 1928, has been reprinted in booklet form, and may be obtained from Messrs. J. and A. Churchill, 40, Gloucester Square, W.1, price 1s. net. The Guide includes lists of hotels, hydros, and other residential accommodation.

THE House and Library of the Royal Society of Medicine will be closed from Thursday, April 5th, to Tuesday, April 10th, both days inclusive.

THE International Labour Office has published six more leaflets (Nos. 82-87) dealing with accumulators (storage batteries), acetylene, aniline, arseniuretted hydrogen, aviation or aviator's sickness, and tetra-ethyl lead. They may be obtained from the director of the London office of this organization, 12, Victoria Street, S.W.1.

THE Rumanian authorities have placed at the disposal of the Privy Council a limited number of invitations to the fifth International Congress on Thalasso-Therapeutics, to be held at Bucarest and Constantza between May 21st and 29th. Applications for invitations should be made to the Privy Council, Whitehall, S.W.1.

THE diphtheria case and death rate for the year 1926 were the lowest ever recorded in the United States, the death rate being 7.5 per 100,000 and the case rate in forty-seven States 80 per 100,000. In 1927 there was a reaction, thirty-seven States showing an increase of 15.7 per cent. over 1926 and 15 per cent. over 1925.

THE French Academy of Medicine has decided to class malonalurea (barbitone) derivatives as dangerous substances falling within the third category of poisonous substances, as laid down by the decree of 1916. This does not necessitate their being kept in special locked cupboards, but ranks them with such drugs as chloral hydrate and the tinctures of digitalis and belladonna. The decision was reached after a recommendation had been received from the Society of Therapeutics, consequent on a case of suicidal poisoning due to one of these derivatives.

THE following appointments have recently been made in the French faculties of medicine: Dr. Debeyre, successor of the late Professor Laguesse in the chair of histology at Lille; Dr. Richou, professor of medical pathology; and Dr. Hamant, professor of clinical surgery at Nancy.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, *British Medical Association House, Tavistock Square, W.C.1*, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are MUSEUM 9361, 9362, 9363, and 9364 (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are:

EDITOR of the *British Medical Journal*, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisera Westcent, London.

The address of the Irish Office of the *British Medical Association* is 16, South Frederick Street, Dublin (telegrams: *Macillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshough Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

## QUERIES AND ANSWERS.

### FLUSHING OF THE HANDS.

DR. A. LEE (Bournemouth) asks for suggestions for the treatment of a case of "red hands" in a married woman, aged 24. The condition is probably due to a vasomotor disturbance, since the hands flush up on the slightest provocation—as, for example, when the patient meets people or takes a mild alcoholic drink; otherwise she enjoys extremely good health.

### MEAT EXTRACTIVES AND GASTRIC JUICE.

"BETA" asks if there is any definite evidence that meat extractives produce an excessive flow of gastric juice, which is usually hyperacid, and therefore causes increased motility of the stomach walls.

### MILROY'S DISEASE.

DR. A. HAWKARD (Leeds) asks for suggestions for treating a case of Milroy's disease, or hereditary oedema of the legs. The patient is a woman, aged 35, and is in good health generally. The condition was first noticed six or eight years ago.

## Remarks

ON

## THE HAEMORRHAGIC DIATHESIS.\*

BY

H. LETHEBY TIDY, M.D. OXON.,

F.R.C.P. LOND.,

ASSISTANT PHYSICIAN, ST. THOMAS'S HOSPITAL; CONSULTING PHYSICIAN,  
ROYAL NORTHERN HOSPITAL.

The title "The haemorrhagic diathesis" includes all varieties of primary purpura. Secondary symptomatic purpura will be referred to incidentally. Haemophilia is not included.

The primary purpuras are divided into two groups: (1) haemorrhagic purpura; (2) anaphylactoid purpura. The first group includes all grades of severity in which the escape of whole blood from the vessels constitutes the essential feature. The anaphylactoid group includes Henoch's and Schönlein's purpura. This group exhibits not only haemorrhages, but also swellings which do not contain blood cells, and is characterized by abdominal pain and colic, and by swelling and pain around the joints.

In urticaria there are similar swellings and pains, but no escape of blood. Urticaria is undoubtedly due to a transient increased permeability of the capillary endothelium. It will be held here that three grades of capillary defect exist—namely, haemorrhagic purpura, anaphylactoid purpura, and urticaria. Variations in the platelets are secondary factors. The term "angio-stasis" is suggested for the group.

## Normal Function of the Platelets.

Two functions are usually ascribed to the platelets. (1) When platelets disintegrate they are said to secrete substances which take part in coagulation of the blood. It is doubtful whether the action of coagulation is of great importance. (2) A function in protecting injured or abnormally permeable capillary endothelium. This is effected by platelets adhering in masses to injured intima, and is partly a mechanical blockage and partly a preparation of blood.

In the circulating platelets are thus affected by (a) a loss equal to the amount of blood escaping, and (b) a special loss owing to their adherence to the weakened spots and consequent destruction, and hence the loss of platelets is out of proportion to the amount of blood escaping. The normal number of platelets is from 200,000 to 350,000 per c.mm. It may vary with great rapidity.

## SYMPTOMATOLOGY OF THE HAEMORRHAGIC PURPURAS.

The principal manifestations to be considered are:

1. The character of the haemorrhages.
2. Coagulation time, and retractility of the clot.
3. Bleeding time.
4. The tourniquet or capillary resistance test (the Rumpel-Leede test). Hess's test.
5. Variations in the number of the platelets.
6. The presence or absence of splenic enlargement.

## 1. The Character of the Haemorrhages.

The haemorrhages may be into the skin, from the mucous membranes, into the subcutaneous tissues constituting ecchymoses, and also a general tendency to bleed easily. The relationship of such conditions as essential haematuria is very important, but will not be here referred to further.

Many entities have been separated from these haemorrhages, such as purpura simplex, purpura haemorrhagica, and many others. Bleeding from the mucous membranes cannot be accepted as distinguishing a special group of purpura. It often occurs from time to time, to a mild degree, in cases which never exhibit any great severity. Neither by the type of haemorrhages nor by their severity can any dividing line be distinguished between the purpuras

in this group. If purpura haemorrhagica is to be separated as an entity from mild chronic purpura it must be on other than the clinical manifestations.

## 2. Coagulation Time.

Results in the literature can rarely be compared owing to differences in the methods. Two general factors influence the normal coagulation time: first, the temperature at which the observation is made; and secondly, the coagulation time varies rapidly in successive drops from the same prick. Christie's results at 37°C. are approximately as follows:

	Normal.	Purpura.
1st drop ...	2 minutes 10 seconds.	2 minutes 35 seconds.
2nd drop ...	1 minute 5 "	1 minute 30 "
3rd drop ...	42 "	1 " 10 "
4th. and subsequent drops ...	40 "	1 " 5 "

In primary purpuras of all grades there is no appreciable increase in the coagulation time. Christie's results show a slight lengthening. Hess has attempted to show that purpuric blood contains in solution the active products of a normal number of platelets which have been disintegrated. His experiments are very scanty and are open to other interpretations, and have been too lightly accepted. It is clear that the absence of circulating platelets does not greatly affect the coagulation time. The clot in purpuric blood may fail to retract normally: this appears to correspond with and be due to the diminution of platelets and is of little importance.

## 3. Bleeding Time.

In this test the blood from a prick is dried off with blotting-paper without pressure every quarter- or half-minute. Normally the bleeding ceases in one to two and a half minutes. It is prolonged in certain circumstances in primary purpura, and may be thirty or sixty minutes or many hours. Evidently the bleeding time and tendency to haemorrhages vary independently of the coagulation time. As to the relationship to platelets, the bleeding time is nearly always normal when the number of platelets is normal. When platelets are greatly diminished the bleeding time is usually markedly prolonged, but this is not by any means invariable. Roskam found in experimental thrombopenia that the bleeding time could be increased to about three times the normal length, but not beyond this. In primary purpura he also found no constant relationship to the number of platelets, and illustrates this by the mean results in two series of cases.

	No. of Platelets.	Coagulation Time.	Bleeding Time.
Series I ...	43,000	5 min. 30 sec.	1 hr. 33 min.
Series II ...	32,000	5 " 50 "	5 "

Spence has found a similar lack of relationship after splenectomy. It will, however, be found that a close relationship exists between bleeding time and the presence of active bleeding. There is clearly a factor common to these and independent of the platelets and coagulation time. This factor must be increased permeability or defect of the capillaries. It is difficult to suggest any other explanation.

The platelets influence the bleeding time by their function of adhering to defects in the endothelium. If platelets are absent, endothelium which is injured by a slight prick, though otherwise normal, will lack their protection, but if present in normal numbers they will protect to some extent even defective endothelium. The observed bleeding time is thus the resultant of the permeability of the capillaries on which it is mainly dependent and of the number of platelets. It shows a close agreement to the amount of haemorrhages occurring at the moment.

## 4. Capillary Resistance or Tourniquet Test.

For this test a tourniquet is placed round the upper arm. In subjects of the haemorrhagic diathesis in the active stages pressure for two to five minutes will produce a crop of purpuric spots in the lower arm. This is also known as the "Rumpel-Leede" or "Hess's test." Hess also introduced a test by subcutaneous injection of saline, which in haemorrhagic stages will provoke haemorrhage. These tests are of more interest than importance.

\* Abstract of paper read before the Section of Medicine of the Royal Society of Medicine on February 23rd, 1928.

5. *Variations in the Number of Platelets.*

The most important general principles which are commonly held may be stated as follows:

1. Platelets are greatly diminished in number or completely absent in the active stages of conditions clinically justifying the term "purpura haemorrhagica."
2. Platelets are not reduced in other forms of purpura—that is, in purpura simplex, anaphylactoid or urticarial purpura, and secondary purpura.
3. During periods of remission of purpura haemorrhagica the number of platelets may rise nearly to normal, but a reduction of platelets precedes recurrence of the haemorrhages.
4. The reduction in the platelets is the essential cause of purpura haemorrhagica.
5. The relation of platelets to haemorrhages is such that when the number is below 60,000 there is abnormal tendency to bleed, below 10,000 the haemorrhages are severe, and below 1,000 fulminant.

These points will now be considered.

1. This is certainly true, and, accepting that platelets adhere to capillary defects, extensive capillary haemorrhages could not exist for any period without a substantial reduction in platelets. Cases of purpura haemorrhagica often have long preceding periods of haemorrhages, which are of the same type, but of less severity, and observations now show that platelets are reduced in these stages to intermediate and various extents. There is no dividing line, either clinical or haematological, which separates the state of purpura haemorrhagica from the milder preceding stages.
2. Investigations in the last few years now show that platelets may undoubtedly be reduced in other forms and grades of purpura; examples in the literature are numerous. This also applies to secondary symptomatic purpura. Patients in this group are always suffering from some serious disease, and hence may be very ill, though the amount of haemorrhage is very slight; in such circumstances a very sick patient with purpura may exhibit little change in the platelets. This will also be shown to apply to anaphylactoid purpura. The evidence can be summed up by saying that platelets show a reduction in numbers when capillary haemorrhages have occurred to any considerable extent, irrespective of the cause.
3. From recorded observations during exacerbations after mild stages the only substantial conclusion that can be drawn is that a rough parallelism exists between the reduction of platelets and the increase of haemorrhages. It is impossible to say which comes first. If, however, the occurrence of haemorrhages is due to the fall of platelets, the converse should be true—namely, that the cessation of haemorrhages is preceded by a rise of platelets. A case of Foerster's shows that this is not so. The patient was in a state of severe purpura with complete absence of platelets. The haemorrhages ceased spontaneously, but it was not until three days later that the platelets showed a rise in numbers. Clearly the cessation of the haemorrhages preceded the rise of platelets.
4. This contention was originally based on the belief that platelets are reduced in purpura haemorrhagica and not in other forms of purpura. This has been proved to be incorrect, but it does not negative the possibility that purpura of any grade is due to reduction in the platelets. With regard to the relationship of platelets to capillary haemorrhages, the following points must be noted:
  - (i) Platelets may be absent from the circulation without the occurrence of haemorrhages. This has been repeatedly recorded in patients who have had previously various grades of purpura, both with and without splenectomy.
  - (ii) An attack of purpura haemorrhagica may pass spontaneously while platelets are still absent.
  - (iii) Both Bedson and Roskam have experimentally reduced the platelets to very low figures without the occurrence of haemorrhages.

Therefore the absence of platelets cannot be the essential factor leading to capillary haemorrhages, and some other primary cause must be present.

5. The evidence given above shows that this statement is incorrect.

6. *The Size of the Spleen.*

The presence or absence of an enlarged spleen will depend on the work which it has to do in dealing with effete constituents of the blood, including red and white cells as well as platelets. The size will depend on numerous factors. When anaemia and leucopenia are advanced there is no reason for the spleen to be enlarged, and, in fact, in such circumstances it is practically never palpable. If the marrow is producing platelets and cells of a low standard a spodogenous enlargement of the spleen results. The size of the spleen is indeed of little importance.

## PATHOGENESIS.

Four structures or tissues must be considered in the pathogenesis of capillary haemorrhages: (1) the platelets; (2) the spleen, which destroys effete platelets; (3) the marrow, which produces platelets; (4) the endothelium of the capillaries, through which the haemorrhages actually occur. Also, in certain circumstances, other portions of the reticulo-endothelium. The marrow and spleen apparently can only affect the haemorrhagic state through the medium of the platelets.

The most prominent recent theories are the following.

- (1) Frank holds that purpura haemorrhagica is an entity distinct from all other purpuras, and is due to an essential thrombopenia caused by lack of formation by the marrow.
- (2) Kaznelson attributes the primary disturbance to overactivity of the spleen, which destroys excessive numbers of platelets.

Both these theories are based on the belief that a reduction in the number of platelets is the essential cause of purpura haemorrhagica. This has been shown to be impossible, and hence some other factor must exist. As the spleen and marrow can only act through the platelets, they cannot constitute the essential cause. An increased permeability from some defect of the capillaries remains as the only possible primary factor.

It is suggested here that so long as the capillary endothelium is normal or intact blood will not escape even in the absence of platelets, but in the event of any defect or abnormal permeability, then the number of available platelets and the maintenance of the supply will become deciding factors in the occurrence and extent of the haemorrhages, the function of the platelets being to adhere in masses to abnormal intima. Bedson's researches give experimental support to this view. He was able to separate two factors necessary to produce purpura in normal animals: (a) an injury to the endothelium which he caused by injections of an appropriate serum, and (b) a reduction of platelets which he produced by injections of agar-serum. Neither of these alone produced haemorrhages. The known phenomena of the primary purpuras, both clinical and haematological, are explicable on this view.

Consider what will occur to an individual in whom the capillary endothelium develops local sites of increased permeability. At first the platelets circulating in normal number defend the weak spots and check the haemorrhages and the associated tendency to an increase in the bleeding time. Adhesion in masses to the threatened spots leads to a fall in numbers, until the platelets are no longer able efficiently to protect all the weak areas. Haemorrhages will then commence and the bleeding time increases. As the platelets fall a vicious circle is established, and the haemorrhages and bleeding time will progressively increase more and more rapidly. The marrow, by responding to the increased demands, may establish an equilibrium at medium stages. Return of the capillaries towards normal at any period will abate the haemorrhagic state and diminish the demands on the platelets: the bleeding time will diminish with this change in the capillaries even before the platelets have appreciably increased. The recovery of the capillaries may be rapid (as occurs in urticaria) or slow, and may be partial. Platelets in varying numbers will still be required and consumed in its protection.

## URTICARIAL PURPURA.

Urticarial or anaphylactoid purpura includes the forms known as Henoch's and Schönlein's purpura. There is extensive clinical evidence of the close relationship between

urticarial purpura, haemorrhagic purpura, and urticaria. Mosler published a careful study. In urticarial purpura swellings occur in which there is no haemorrhagic factor, and there are also two varieties of superficial haemorrhages: (a) purpuric spots, scanty in the early stages; (b) areas of ecchymoses into the swellings. Appearances similar to the latter can be produced in haemorrhagic purpura by the subcutaneous injection of saline. The haemorrhages in this test are produced by distension causing injury to capillaries of reduced efficiency, and thus differ from true purpuric spots.

A patient with Henoch's syndrome is sick at the onset, not from the purpura, but from the urticaria. He is more sick than purpuric, and there may be little fall in the platelets. A slight increase in the capillary defect leads to the same position as in haemorrhagic purpura, and the case is often said to have changed from Henoch's purpura to thrombopenia and purpura haemorrhagica.

Splenectomy should be considered in this group as in other forms of primary purpura, and it is unjustifiable to say that operation is contraindicated.

#### SPLENECTOMY.

The results of this operation are extraordinarily good, except in the acute cases, which would probably die in the absence of operation. In many of the chronic cases there is an immediate cessation of the haemorrhages and a rapid rise in the number of platelets. A similar rise in platelets occurs after splenectomy for other causes and when performed experimentally in animals. There is also a rise, though of a greater extent, in the number of leucocytes, and within twenty-four hours the number of polynuclear cells alone may exceed 30,000 per c.mm. Such a rise cannot be ascribed to the absence of the destructive action of the spleen, and the immediate rise both of leucocytes and of platelets must be due to flooding of the blood with reserves from the marrow. The immediate cessation of the haemorrhages is due to this large number of platelets being sufficient to protect the sites of capillary defect. This obvious explanation is supported by Bedson's experiments.

This is the most favourable, but not invariable, course after splenectomy. The results may be summarized in the following five groups:

1. Platelets rise high and then fall to about a normal level. Haemorrhages cease, and do not return.
2. Platelets rise, but subsequently fall to a very low level. Haemorrhages cease, and do not return.
3. Platelets rise and fall as above, but haemorrhages return in varying degrees.
4. Platelets fail to rise to any great extent, but haemorrhages cease.
5. Platelets fail to rise, and haemorrhages continue.

These different courses depend on variations in the following factors:

- (i) The degree of capillary defect, and its transient or permanent nature.
- (ii) Condition of the marrow.
- (iii) Alteration in the platelet circulation due to the absence of the spleen.

With regard to the last, it may be accepted that in the absence of the spleen the tissues which undertake its functions work at a lower standard. This is undoubtedly what occurs in acholuric jaundice. Fewer platelets will thus be destroyed by the marrow and a larger number available for the protection of the capillaries. This is a permanent gain.

The capillary defect may pass during the period of high protection after splenectomy, or it may only pass partially and still require protection by platelets, resulting in the subsequent fall. The platelets may or may not be sufficient to prevent the haemorrhages, thus accounting for the second and third courses.

The marrow may be already denuded of reserves, and hence the initial rise will not occur, or only partially. Courses 4 and 5 will follow in these circumstances, depending on the recovery of the capillary defect and the platelets available.

The various courses which follow splenectomy can thus be followed on the theory that the primary defect lies in the capillaries.

#### TREATMENT.

##### Splenectomy.

In view of the successful results following splenectomy the essential question in treatment is when the operation should or should not be advised.

1. *Acute Cases.*—The mortality here is very high, but a study of the cases in conjunction with our knowledge of their normal course suggests that the fatal cases would probably have died without the operation.

2. *Chronic Cases.*—It is here that the results have been so good, and the only questions arising are as follows:

(i) Is the condition such that in the absence of operation life can continue without serious impediment or risk? A certain number of cases obviously fall into this category. The decision is often easy, but in doubtful cases many points have to be taken into consideration—that is, the extent of the haemorrhages, their duration, and any evidence of increasing severity, the degree of anaemia, and evidence of strain on the marrow, as shown by leucopenia.

(ii) With regard to the remainder, for what reasons should operation not be advised?

(a) As regards direct operative risks, this depends on the usual risk of any major operation, but especially on the degree of anaemia and the risks of heart failure or thrombosis. These risks possibly may be diminished with greater experience with the operation. The rapid rise in platelets may dispose to thrombosis.

(b) What cases will do badly if they survive? This will depend on (1) excessive permeability of the endothelium, and (2) aplasia of the marrow. With regard to the permeability, the extent of the haemorrhages is little guide, as many extreme grades do well. The duration of the bleeding time may prove to be a better guide, but at present observations have not been very accurate; possibly up to thirty minutes is consistent with a good outlook. With regard to aplasia, the number neither of platelets nor of red cells is a guide. Observations suggest that if the total number of polymorphs is definitely below normal a good result cannot be anticipated, but even in these circumstances there is no evidence that splenectomy makes the patient worse.

3. *Urticarial Purpura.*—The patient here is sick primarily because he is urticarial, and not because he is haemorrhagic; yet it may be suggested that the existence of purpura or bleeding of more than a trivial degree is an indication for splenectomy, whatever be the number of platelets.

##### Transfusion.

Transfusion may completely abort an attack, but usually the improvement is only temporary. Unfortunately suitable donors must be chosen with special care for purpuric subjects.

##### Blockade of the Reticulo-Endothelial System.

It is generally accepted that the immediate effects of splenectomy are due to the flooding of the circulation with platelets, whatever may be the origin of this occurrence. The question arises whether this effect can be produced by any less dangerous methods than an operation. Bedson found that a certain definite rise in platelets followed splenectomy. He found also that an equal rise followed injections of Indian ink, designed to block the reticulo-endothelial cells. The evidence points to the rise in platelets being identical with that which follows splenectomy, for if this operation is performed immediately after the blockade has raised the platelets no further increase occurs. It is reasonable to suppose that these injections will produce a similar rise in human beings and a similar effect, at least temporarily, to that of splenectomy.

#### CONCLUSIONS.

1. Increased permeability or defect of the capillary endothelium is the essential cause of the haemorrhages in the haemorrhagic diathesis.
2. Alterations in the number of platelets are secondary to the capillary haemorrhages.
3. The haemorrhagic purpuras form a single group, and

are only separated from urticarial (anaphylactoid) purpura and urticaria by the degree of the capillary defect.

4. Splenectomy should have a permanent beneficial effect, though protection from capillary haemorrhages may not be complete.

The term "angio-stasis" is suggested for the condition.

## THROMBO-PHLEBITIS MIGRANS.

BY

T. GILLMAN MOORHEAD, M.D., F.R.C.P.I.,

REGIUS PROFESSOR OF PHYSIC, DUBLIN UNIVERSITY;

AND

LEONARD ABRAHAMSON, M.D., F.R.C.P.I.,

HONORARY VISITING PHYSICIAN, MERCERS' HOSPITAL; PROFESSOR OF PHARMACOLOGY, ROYAL COLLEGE OF SURGEONS IN IRELAND.

PHLEBITIS of widespread distribution, recurrent and migratory, has been described from time to time. In most of the descriptions we find an association with various suggested etiological factors. As far back as the time of Paget, Lancereaux, and Hewitt we find reports of a number of cases in which gout was invoked as the exciting cause, though often with but scant justification. Dagnillon<sup>1</sup> described a series of cases of migratory phlebitis in 1894, and regarded the condition as an indication of "an arthritic constitution, with or without actual gout." In a case published by Neisser<sup>2</sup> in 1903 there was a clear-cut history of syphilis, whilst in two cases recorded by Schwartz<sup>3</sup> in 1905 there was advanced pulmonary tuberculosis. In other cases of more or less widespread phlebitis we find an association with various conditions, such as rheumatic fever, trauma, and a number of toxic and cachectic illnesses.

The first description of a type of recurrent phlebitis in which no causal factor could be adduced, and which possessed individual and constant symptomatic features, was made in 1905 by Briggs,<sup>4</sup> who thought that the cause was possibly to be found in a sclerosis of veins analogous anatomically with arterio-capillary fibrosis.

The type of phlebitis which we are about to describe, and of which we have seen four cases, differs from that of Briggs and other writers in that in each patient there was definite evidence of involvement of visceral veins as well as of peripheral veins. These cases had so many unusual features in common that we were led to the conclusion that we were dealing with a rare type of phlebitis *sui generis*, to which we could find but little reference in the English literature.

### Case Histories.

#### CASE I.

A lady, aged 55, suffered from an illness diagnosed as pleurisy in September, 1926. Early in October she was bitten by a mosquito on the left hand, but no local septic symptoms developed. A week later she got extensive thrombosis of the left cephalic vein. In another week the veins of the right arm became involved, and ten days later there was extensive dry pleurisy, involving mainly the right lung, but also the base of the left. Throughout there was mild pyrexia. This cleared up slowly, and the patient was progressing favourably when, three weeks later, there was an attack of violent abdominal pain, with collapse and accompanied by severe melaena. The patient at this time was extremely ill, and mesenteric thrombosis was diagnosed. Recovery took place, and everything seemed well, when, after an interval of a month, the left saphenous vein became thrombosed. Subsequently the right saphenous vein was also involved. Finally, a branch of the facial vein became affected, and was followed by some ulceration of the mouth, this event occurring about six months after the beginning of the illness. Each attack of phlebitis was accompanied by fever, but in the intervals the patient was fairly well. Apart from the facts above stated nothing abnormal was found. A blood culture was sterile; the heart, kidneys, and other organs were normal. Various treatments were employed, including peptone injections and a vaccine made from streptococci isolated from the teeth. It was not apparent that any treatment had any special effect on the course of the disease, apart from relieving symptoms. Since the involvement of the facial vein the patient had made slow but satisfactory progress, and is now, twelve months later, except for some persistent oedema of the legs, practically well.

#### CASE II.

A strong healthy man, aged 62, who had had no previous illness of importance during the last twenty years, suffered towards the end of July, 1927, from a mild pyrexial attack. This was accompanied by abdominal discomfort and slight pain. The possibility of appendicitis was discussed, but in a couple of days the attack cleared up, and a week later the patient went on a holiday. On the first day of this holiday he walked about three miles, and that evening felt discomfort in his right leg. Two days later the leg was swollen, and there was obvious phlebitis of a superficial vein in the calf. The temperature was raised, and remained slightly above normal for one week.

After three weeks' rest the patient returned home, and after a further couple of weeks resumed work. Soon after, the right leg, which had returned to normal, again became swollen and tender, apparently due to thrombosis of the deeper veins. A week later a small vein in the left calf became thrombosed. This settled down in a fortnight, and the patient was apparently going on well when pain in the left side of the thorax developed, and a pleural rub at the base of the left lung was detected. This was accompanied by a smart fever and haemoptysis, and as the sputum was found to contain pneumococci in pure culture, a diagnosis of mild pneumonia was made. After five days the attack cleared up, but haemorrhagic sputum continued for about a fortnight.

The next event was an attack of abdominal pain with flatulence, followed by thrombosis of the right saphenous vein, and again mild pyrexia. This attack subsided, and the patient was sent to a nursing home for full examination. A complete x-ray examination revealed nothing abnormal, a blood culture was sterile, and the Wassermann reaction negative. Mild anaemia, but nothing else, was found on full examination of the blood. The urine was sterile, and contained nothing abnormal, and a complete examination of the faeces showed nothing wrong.

Just as this examination was complete, pain was again experienced over the left lung, and another attack of apparent pneumonia developed, again accompanied by some haemoptysis. Five days after the subsidence of this attack there was a severe bout of anginal pain, believed at the time to be due to thrombosis of a cardiac vein. This was accompanied by a very rapid fibrillating pulse. When this attack had subsided the patient again returned home, and the day afterwards had a further pneumonic attack, in which the base of the right lung was involved.

The last event in this long illness was an attack of violent abdominal pain, so violent as to produce complete collapse. This came on in the evening and lasted several hours, and although no melaena followed, it was diagnosed as an attack of mesenteric thrombosis, owing to its resemblance to a similar attack seen in Case 1, in which melaena was a prominent symptom.

During the whole of the illness, which lasted about six months, and which included eleven thrombotic episodes, the patient was depressed and felt ill, and suffered from lassitude. He looked anaemic, and there was marked loss of weight. A week after the abdominal attack his spirits began to improve, and his tongue, which had been furred all through, became normal. From this time on he made a slow but satisfactory recovery.

#### CASE III.

This patient, a woman, aged 50, had enjoyed robust health until the month of June, 1924, when she developed phlebitis in the region of the left foot, with resultant pain, tenderness, and swelling. This attack was the precursor of many similar attacks, which came on at varying intervals and affected the veins of the left leg, left thigh, and later those of the right ankle and leg. With each attack there was mild pyrexia. In addition to involvement of superficial veins there was implication of deeper veins, with marked oedema. The patient spent five weeks in bed, and for nine months rested for most of the day on a couch.

In April, 1925, phlebitis attacked the veins of the right hand, which became painful and tender. Shortly afterwards the left hand became affected. On September 30th, 1925, the patient was admitted to hospital for investigation. The ankles were oedematous, and the skin of the legs was thick and discoloured, showing the appearance seen frequently after a severe attack of phlebitis. Over the inner aspect of the thigh a number of nodules could be felt, with a distribution corresponding to the course of the large saphenous vein. Blood culture was negative. There was severe pyorrhoea, and culture from the gums yielded a pure growth of *Streptococcus viridans*. Teeth extraction was advised, and a vaccine prepared from the gums.

Improvement continued until December, 1925, when the patient developed symptoms and signs similar to those of a mild pneumonic attack. This was accompanied by haemoptysis and by moderate pyrexia, and necessitated a month's stay in bed. Shortly afterwards phlebitis developed in a vein of the left arm. This was followed by a further remission, which lasted until the month of June, when some pain, tenderness, and swelling developed in the flexure of the right knee. No further attack has occurred since.

During her illness the patient experienced considerable malaise, loss of appetite, and general deterioration of physical strength. As residua of the recurrent attacks there is a tendency to the development, after exertion, of swelling of the ankles, especially on the left side, and to stiffness of and pain in both legs, after even moderate exercise.

#### CASE IV.

A nurse, aged about 22, got a superficial burn on the left ankle in February, 1922. Three months later there was extensive thrombosis of the superficial veins of the left leg, with pyrexia. This cleared up, but was followed two months later by thrombosis

of practically every superficial vein of the right leg. A section of a vein was removed for examination and showed a firmly adherent clot, with slight thickening of the vein wall. Cultures made from the vein were sterile. An absolutely complete examination at this time failed to reveal any cause for the trouble. Further events in this case were thrombosis of a superficial vein in the abdominal wall, and of one or two other superficial veins of the trunk at intervals of two or three months, each attack being accompanied by a general febrile reaction. Finally, a year after the beginning of the illness, the right popliteal vein became affected. In this case no involvement of visceral veins took place; but recovery was very tedious, and the patient was only able to resume work about two years after the beginning of her illness. Various treatments, including colloidal manganese and peptone, were employed, but do not require detailed comment.

It will be seen that the main feature of these cases is the tendency to metastatic extension, often at long intervals. The trouble commences in a segment of a peripheral vein, which becomes painful and tender. Redness and swelling ensue, and there is slight or moderate pyrexia. Soon the symptoms begin to subside, only to reappear in some portion of the same vein or of a distant vein. All four limbs may be involved, and with each recurrence of phlebitis there is a recurrence of pyrexia.

In association with the tendency to extension we note implication of visceral veins. Thus the pulmonary involvement with haemoptysis, noted in three of our cases, was referred by us to a process in pulmonary veins similar to that met with in the peripheral veins. Embolism was negatived by the definite absence of characteristic symptoms associated with this condition. In this connexion we would like to stress the conspicuous absence of embolic symptoms in our cases, though the patients were not confined to bed throughout their illness, and must therefore at one time or another have been in a condition most favourable to the production of embolus. In two of our cases symptoms of mesenteric thrombosis were encountered, and in one patient symptoms occurred which suggested involvement of a coronary vein. This implication of a coronary vein is unique so far as the literature is concerned, though it seems likely that the paroxysm of tachycardia in a case described by Legrand<sup>5</sup> was due to this cause.

The etiology of the condition is obscure, though the local signs of inflammation and the method of spread suggest forcibly the presence of a blood infection. This view is strongly advocated by Vaquez and Leconte,<sup>6</sup> and later by Legrand,<sup>7</sup> in connexion with a series of analogous cases described by them under the title "subacute venous septicaemia." Legrand quotes two cases in which the streptococcus was isolated from the blood stream. In our cases blood culture was uniformly negative, but was not repeated with sufficient frequency to permit definite conclusions. In one case severe pyorrhoea was present. Apart from this no septic focus was found in any of our patients.

The disease follows a prolonged course with alternations of remissions, more or less complete, and of subacute recurrences. The ultimate prognosis seems to be favourable, though functional disability may persist. It is interesting, though perhaps inapposite, to draw attention to cases quoted by Buerger<sup>8</sup> in which recurrent phlebitis of superficial veins was the precursor of thrombo-angiitis obliterans. Such a sequel has not been encountered by us, and it is likely that Buerger's cases did not belong to the group with which we are dealing.

#### Summary.

We publish four cases of phlebitis of extensive distribution and migratory character, showing involvement of peripheral and visceral veins, prolonged course, and relative benignity. We can throw no light on the etiology, but present our short paper in the hope that it will stimulate research which will elucidate the cause of this unusual but interesting malady, and place therapeutic efforts on a scientific basis.

## THE HISTORY OF AN OUTBREAK OF TYPHOID FEVER IN PRETORIA:

WITH SPECIAL REFERENCE TO THE DETECTION OF TYPHOID CARRIERS.

BY

ADRIANUS PIJPER, M.D.,

PATHOLOGIST TO THE PRETORIA HOSPITAL (AT THE TIME ACTING M.O.H. OF THE MUNICIPALITY OF PRETORIA),

AND

B. DAVIDINE PULLINGER, M.B., B.S.

THE history of this outbreak is of interest in that it illustrates the necessity of empowering medical officers of health to exercise a closer supervision of dairies than has been the case hitherto, especially so far as the native element in such places is concerned. It also shows the superiority of the complement-fixation test over the agglutination test of Widal for tracing the course of an outbreak and discovering carriers.

The total number of cases in this outbreak was twenty-eight, including seven among natives. Only one patient died, a European female child, one of the first to be infected. This low mortality is probably due partly to the prompt recognition of the disease in the later cases, when medical practitioners and the public were aware of the probability that slight illness in a family supplied by the incriminated dairy would probably turn out to be typhoid fever. The typhoid case mortality in Pretoria is ordinarily about 7.5 per cent.

The first patient was a European boy. The usual inquiries were made as to the supply of milk and food to the household, but since nothing suspicious was found, and it was said that the child drank very little unboiled milk, no further steps were taken. Quite a different light was thrown on the matter, however, when, two days after this child had been notified (complement-fixation test positive, Widal test positive, typhoid bacilli recovered from blood), the daughter of the proprietress of the dairy which supplied this household, who had been ailing for some time, was subjected to a typhoid complement-fixation test, and her reaction was found to be positive. This patient was removed to hospital as soon as the diagnosis was established, and on the same day blood specimens were taken from the eleven natives employed at the dairy, who were all "healthy" and at work. The result was surprising, for seven of them reacted positively to the typhoid complement-fixation test. Of these seven, five were strongly positive, one just positive, and one weakly positive. Widal tests were performed at the same time, but only two positive reactions were obtained: the serum of one boy, which was definitely positive with the complement-fixation test, agglutinated only in serum dilutions up to 1 in 20, while the serum of the boy whose complement-fixation reaction was just positive only reached 1 in 40.

This large number of positive findings made the position very difficult. From past experience we know that carriers as a rule give a positive complement-fixation reaction, but we also know that this test remains positive for a varying period after convalescence. It seemed absurd to assume that seven out of eleven natives employed at one dairy were carriers. A much more probable explanation of the situation was that there had been a local epidemic at the dairy among the native servants, and that we were concerned with the tail-end of this epidemic. Interrogation of the proprietress and the natives at first seemed to elicit facts which supported this view. There was a vague history of several of the natives having been down with "malaria" off and on during the previous weeks, and having been dosed with quinine for that reason; and there was also a tale of a young native who had been engaged two or three months before this trouble started, but who had never done any work and had been either malingering or ill most of the time. This rather imaginary young native had now disappeared, and all our attempts to trace him proved in vain. Moreover, the more we pressed for further details about the illnesses of the natives in the past weeks the more vague, confused, and unreliable the information became. There

evidently existed a marked reluctance to assist us in clearing up the position.

We therefore put our own construction on the matter and dealt with it in the following way. All the natives except one were removed to the isolation hospital on the same day on which their blood tests had been performed, on the strength of a magistrate's order procured for the purpose. The one native left behind gave a negative test, and had been employed at the dairy for sixteen years. It was assumed that when a native has worked at a dairy in town for that period, and is exposed to typhoid infection without harm, he is either naturally immune or has become so by having had the disease. That he was the carrier responsible for the whole outbreak was highly improbable for the same reason, and also because he gave a negative complement-fixation reaction. Moreover, as this boy had been in the dairy's employ for so many years, he would be very valuable to his employer, who was considerably disconcerted by the removal of all the other natives, and who naturally experienced great difficulty in carrying on her business. Still, this was better than closing the dairy altogether.

The rather drastic measure of removing all the natives was, in our opinion, warranted on the grounds that there evidently had been, or was at present, an outbreak of typhoid fever amongst the native employees, and that at any rate those who reacted positively had something to do with the outbreak; that there might very well be a carrier amongst them; and that, further, those four boys who gave a negative reaction might have become infected quite recently, so that removal of only the obvious cases would not have the desired effect of stamping out the infection. Taking away obviously infected natives and leaving behind a few possibly or even probably infected ones would have been a half-measure that might easily have undone whatever would have been achieved by the steps taken. It was also found that the native quarters at the dairy were not in good condition, and that when once infection had started there probably every native would fall a victim to it.

That the measure of removing all the natives was not too drastic became evident three days later, when two of the natives developed manifest typhoid fever at the isolation hospital. These were the two boys who had given a weakly positive and a just positive complement-fixation reaction.

The other measures taken to prevent the further spread were: disinfection of the dairy premises and the sending of a written warning to all the customers of the dairy to boil their milk. Naturally this last measure was not, strictly speaking, necessary. If the source of infection had been removed, as we believed it had, there was no need to boil the milk; it was thought, however, that with such a large number of infected natives at the dairy some infectious material might still persist, notwithstanding thorough disinfection of the premises, and that therefore the boiling of the milk might help to destroy any source of infection that remained.

It may be stated at once that the measures taken were quite successful, though the mischief had been done before they were put into force. During the ensuing fortnight an unusually large number of typhoid notifications reached the health office at Pretoria. These cases were investigated with particular care. With very few exceptions (and these were chiefly persons from outside the town) all the cases could be traced to the consumption of milk from the incriminated dairy. In all cases except one the patients were customers of the dairy; in that one case the patient was in the habit of drinking milk at a teashop which was supplied by the dairy. The large majority of patients informed us that they usually drank their milk unboiled; in two instances the only person in a household to contract the disease was the one who insisted on taking his milk unboiled, whilst the other members preferred it in the boiled condition. Still, considering the risks of infection run by the public in those days—as, for instance, the man who contracted typhoid through drinking milk at a teashop—one is impressed by the relatively small number of persons who contracted the disease. Even if allowance is made for a fairly large number of "ambulatory" and otherwise undiagnosed cases, the conclusion

is inevitable that there must exist a pretty widely spread immunity against the disease.

The removal of the natives had the desired effect of extinguishing the source of infection. A fortnight after the natives were removed the notifications came to an end. Several weeks later a child in a family supplied by the dairy was found to be ill with typhoid, but closer investigation showed that in this family another child had been ailing for many weeks, without the true cause being suspected, and that this other child had become ill at the same time as the large crop of victims of the outbreak. The dairy could therefore only be held indirectly responsible for this late case.

Notwithstanding the fact that only one case terminated fatally, the disease was not of a mild type. Relapses were fairly frequent, the disease lasted the usual time in most cases; and although, as always happens, some cases were very mild, there were also several in which the life of the patients was seriously endangered. A complement-fixation test was performed in all cases but one, and was uniformly positive. Blood cultures were attempted four times with a pure growth in each case. In addition, Widal tests were performed on four patients and were positive in only two.

To return to the natives who had caused the outbreak. It has already been stated that two of them showed manifest symptoms of typhoid infection three days after they were removed from the dairy; their disease ran a normal course. Of the other eight, the three who gave negative complement-fixation reactions at the start remained negative. Complement-fixation tests were performed once every week on all these natives; in addition to this, regular weekly examinations of the stools and urine were instituted.

The unpleasantness and difficulties of repeated stool examinations are considerably relieved by adopting the following technique. Strong glass rods are made, about 1 cm. thick and about 15 cm. long, with rounded ends. At about 1 cm. from one of the ends a hole, about 2 mm. wide, is drilled across the rod, care being taken that the edges of the hole are left smooth. The rods are inserted into test tubes, with a plug of cotton-wool in the mouth of the test tube, just like diphtheria swabs, and sterilized in this position by hot air. A sample of stool can now be obtained from any patient at a moment's notice by taking the glass rod from the test tube, inserting it into the patient's rectum (vaselining is not necessary), turning it round a few times, and, after withdrawal, replacing it into the test tube. Sufficient material will always find its way into the drilled hole.

It would have been of considerable interest if these stool and urine examinations could have been performed immediately after removal of the natives. Pressure of other work prevented this, and it was thought more advisable, both with a view towards preventing further spread among these natives and in order to make a possible carrier amongst their number harmless in the shortest possible time, not to lose time over examinations, but to institute preventive treatment without delay. In Pretoria we have so far obtained very good results from the use of the Besredka method of immunizing against typhoid. It seems to have definite prophylactic value, and also an undoubted effect on "stool carriers." On three consecutive mornings each person takes one bile pill, followed by a pill containing 40,000 million typhoid bacilli, killed by heat. (Paratyphoid bacilli are not included because this infection is practically non-existent in this region.) This treatment was given to the isolated natives a couple of days after arrival at the isolation hospital. It probably assisted in keeping the natives with negative blood tests free from infection, although here also the improvement in sanitary conditions, as compared with those obtaining at the dairy, must have had an influence.

When the first stool and urine examination was made it was found that not one stool of the eight yielded typhoid bacilli. In one urine typhoid bacilli were detected in large numbers. This native had been engaged by the dairy six months previously, and had acted as stable and delivery boy. As the infection had only spread from the dairy quite recently, it must be concluded that this native had arrived at the dairy in a perfectly sound condition, and that he had contracted the infection at the dairy. He had

a strongly positive complement-fixation reaction for typhoid, but his Widal reaction was negative from the start, and remained so for some weeks after. The three natives who persistently showed negative blood reactions and negative findings in both urine and stools were discharged from the isolation hospital after four weeks and returned to the dairy. It was thought that one might rely, if not on their natural immunity, then on the immunity acquired from the Besredka prophylactic treatment. This left five boys, one of them the urinary carrier, and the four others giving positive complement-fixation but negative Widal reactions, and negative findings in stools and urine. After the urine and stools had been examined five times, and it had been noticed that during these weeks their complement-fixation reactions had become weaker and weaker, it was considered that it was safe for them to return to work, and they were allowed to resume work at the dairy. The only one then left over was the urinary carrier; his blood gave a persistently positive complement-fixation reaction, and his urine every week showed typhoid bacilli. It was not to be expected that Besredka treatment could have had any effect on this condition. Treatment was therefore instituted with ordinary typhoid vaccine given under the skin, and large doses of urotropine, but after many weeks, although the typhoid bacilli in the urine showed signs of diminishing in number, they were still to be found. It took four months before they disappeared entirely and the boy could be discharged.

This constitutes the history of the outbreak. The moral of the story is that if the first case of typhoid at the dairy had been recognized as such—whether it was the imaginary stray young native or a member of the regular staff—much suffering and unhappiness would have been prevented. Our dairy by-laws place the obligation on dairy owners to notify the health department of any case of infectious or contagious disease occurring on their premises; it is evident that this is an unsatisfactory arrangement. The onus thus rests on the health department to prove that the dairy owner was aware of the fact that a disease amongst the personnel was infectious or contagious, and that will always be difficult. The whole responsibility should be transferred to the health department, provided that at the same time it receives the powers and facilities to examine all employees upon their being engaged by the dairy, and at regular short intervals thereafter. This examination should include a blood test for typhoid fever, and the foregoing record amply shows that for such work the complement-fixation test is superior to the Widal. If the Widal test had had to be relied on the urinary carrier would not have been detected with the same rapidity, and where two other natives at the time gave a positive Widal reaction the investigation would probably have stopped at that, and the chief culprit would have carried on his work.

It remains to give a brief description of the principles and technique of the complement-fixation test for typhoid. We have for many years insisted on the necessity of abandoning agglutination tests for typhoid in South Africa, as we have proved<sup>1,2</sup> that the majority of cases cannot be diagnosed by this method. We have also obtained some evidence from animal experiments that this failure to develop agglutinins which we have demonstrated in South Africa is at least partly due to the prevailing excessive sunlight.<sup>2</sup> The complement-fixation test is positive in over 90 per cent. of cases, is as a rule not positive in persons who have been vaccinated against typhoid but are suffering from some other infectious disease, becomes positive at an early stage of the disease, and is much more helpful in the detection of carriers. Its only drawback is that it requires perfect technique and much more care than agglutination tests. Our present procedure is as follows.

The antigen is prepared by cultivating typhoid bacilli (there is no difference between typhoid strains for this purpose) on ordinary agar slopes for twelve to twenty-four hours and washing them off with saline solution, using about 4 c.c.m. per slope. The suspension is heated in the water-bath at 57° for one hour, stored in the ice-chest for forty-eight hours, and filtered through a Berkefeld candle. The filtration must be slow and produce only a few cubic centimetres per hour. Suction may not exceed 16 mm.

of mercury. It is only by strictly observing these rules that a potent and constant antigen can be prepared. Each filtrate must be titrated afresh with each new haemolytic system to be used. This is done by employing diminishing quantities of filtrate, from 0.5 c.c.m. to 0.05 c.c.m., with 0.5 c.c.m. of guinea-pig complement diluted ten times, making up to 1.5 c.c.m. with saline solution, incubating for one hour, and then adding 1 c.c.m. of haemolytic system. A control tube is required which contains only saline and complement; to this tube also 1 c.c.m. of haemolytic system is added. The time is noted when this control tube has cleared, and ten minutes after this the tubes are again inspected. The tube which then shows complete haemolysis and contains the largest quantity of antigen indicates the quantity of antigen to be used in the test proper. The antigen is then diluted so that 0.5 c.c.m. contains the suitable dose. As a rule we find that 0.3 c.c.m. represents the quantity of antigen to be used.

If the filtrate is to be kept for more than a few days it is advisable to add 0.25 per cent. carbolic acid to the filtrate previous to titration. A good filtrate has considerable keeping qualities, and although we do not use it after it is fourteen days old we have found that it will keep its antigenic properties for at least thirty days.

We prepare haemolytic system by determining the minimum quantity of a sheep's cells-rabbit serum which, in the presence of 0.5 c.c.m. of ten times diluted guinea-pig serum, will completely dissolve in two hours 0.5 c.c.m. of a 5 per cent. suspension of sheep's cells, the total volume in each tube being made up to 2.5 c.c.m. Four times this minimum quantity of serum is then used in the test proper. The serum is suitably diluted for this purpose with saline, and equal quantities of diluted serum and 5 per cent. sheep's cells suspension are mixed.

The patient's serum is inactivated, and 0.1 c.c.m. is put up with 0.5 c.c.m. antigen, 0.5 c.c.m. complement 1 in 10, and 0.4 c.c.m. saline. This is incubated for one hour, and then 1 c.c.m. of haemolytic system is added. At the back of every patient's tube is a serum control, containing 0.2 c.c.m. of the patient's serum, no antigen, 0.5 c.c.m. complement, and 0.8 c.c.m. saline. In addition an antigen control, containing 0.5 c.c.m. antigen, 0.5 c.c.m. complement, and 0.5 c.c.m. saline, is put up.

Readings are taken when the antigen control has cleared, and then for every individual patient when his serum control tube has similarly cleared. Serums from the later stages of the disease show complete and lasting fixation; those from earlier stages show partial fixation, which is often not permanent. It is useful to include a known positive serum in the series, either from a previously tested typhoid patient or from an injected rabbit.

Human serum which produces complete fixation under these conditions will retain that quality when kept at room temperature for a considerable time.

By following this technique we have been able to make a positive serological diagnosis of typhoid fever in cases where the presence of the disease was established beyond doubt by positive blood cultures, but where Widal's agglutination test was persistently negative.

We have found the method particularly valuable in the detection of carriers. Here we also often found a negative Widal and a positive complement-fixation reaction, as illustrated by the case recorded in this paper.

## THE ROLE OF DEAD AND INFECTED TEETH IN AUTOGENOUS INFECTIONS.

BY

A. P. BERTWISTLE, M.B., Ch.B., F.R.C.S.Ed.

WHILE the literature teems with works on the evil effects of pyorrhoea alveolaris—and there can be no doubt as to its baneful effect on health—there is another dental condition which is but now receiving the attention it deserves—namely, the tooth which has died before or after filling, and which has subsequently become infected. That death may occur without pain makes the condition all the more unsuspected.

The bacteria in pyorrhoea pass into the mouth, where the majority are ingested by the salivary corpuscles; the rest pass on to the stomach and are destroyed, if the gastric juice is normal. In the case of the filled tooth the bacteria cannot regain the mouth by way of the original decay, but must enter the bone, from which they or their toxins may be disseminated by the blood stream to all parts of the body, when those tissues which are "helo par" fall a prey to them. By the irony of fate it is those people who take care of their teeth, having no untreated caries, who

are often the sufferers. The following references to clinical cases will illustrate these points.

**Case 1.**—A man, aged 27, had thrombosis of the posterior tibial venae comites. Five years later he developed the first of a series of eight or nine attacks of the lymphangitis which precedes elephantiasis. The whole course of the lymphatics accompanying the saphenous vein and the superficial inguinal glands became inflamed for a period of about a week. Though there were no obvious caries one tooth was bluish, and x-ray examination showed an area of rarefaction at its root. On opening the pulp pus welled up, and the tooth was removed. Another attack, differing somewhat from the others, occurred a year later, and two days after its commencement a tooth crowned by the old method without root treatment became slightly tender for a day. An attack of fibromyositis occurred; this had been frequent before the first extraction, but had not been experienced since. X rays showed no abnormality. The tooth was removed, however, and a granuloma was found at the root which yielded *Streptococcus salivarius* and diphtheroid bacilli. The pulp cavity was found to be full of greenish pus from which was obtained a scanty growth of *Staphylococcus albus*. There has been no return of the fibromyositis or lymphangitis in the nine months which have elapsed, and the oedema has been less marked.<sup>1</sup>

**Case 2.**—A man with arthritis of the left knee was treated by rest for two years, followed by manipulation, which caused a "flare-up." For two more years walking was only possible with the aid of a stick. Attention was accidentally drawn to a tooth which had been stopped, and an x-ray examination showed apical rarefaction of this and of an adjacent tooth. These teeth were extracted, and a course of antistreptococcal vaccine instituted. The joint gave no further trouble for five years, when two more teeth showed apical rarefaction. After their removal the joint cleared up at once.

**Case 3.**—A man, aged 62, had been afflicted with osteitis deformans for twenty years; the other tibia, right humerus, clavicle, and head became involved later. The teeth were very foul, and much pyorrhoea alveolaris was present; this condition must have existed for many years, and probably dated from the time of onset of the osteitis. All the septic teeth were extracted, large masses of granulation tissue were removed, and portions of bone from the upper alveolus, including a local enlargement, in order to lessen the deformity. The skin over the tibiae, which had become oedematous and inflamed, speedily cleared up, and the bone lost its tenderness.<sup>2</sup>

**Case 4.**—A married woman, aged 35, came for dental treatment seven years ago, at which time she was suffering from tenosynovitis of the wrist. There were three dead teeth, and the gums were badly infected, streptococci being recovered from them. On removal of the dead teeth, six months later, the synovitis disappeared, though streptococci were still present in the gums.<sup>3</sup>

**Case 5.**—A woman, aged 65, had fibromyositis of the neck muscles and cervical spondylitis deformans, leading to much limitation of movement. The removal of two dead teeth caused considerable improvement, but she refused to have other dead ones out.<sup>3</sup>

**Case 6.**—A man, aged 45, had for two years suffered from sciatica, which failed to respond to vaccines or sunlight. He had two dead teeth, which were extracted, one yielding a pure culture of *Streptococcus longus*. The socket did not heal readily, and whenever pus accumulated in it he had an exacerbation of his sciatica, which was promptly relieved by opening up the socket.<sup>3</sup>

**Case 7.**—A young woman with dyspepsia and anaemia had fleeting joint pains accompanied by slight swelling. The appendix was removed and found to have an abscess at its tip, but her condition did not improve. Two years later she began to have an evening rise of temperature, associated with severe nasal catarrh. A radiogram showed a rarefied area at the tip of a filled dead tooth, which was extracted. After three rigors, during each of which the socket became painful and inflamed, her health improved greatly, and the "rheumatic" pains and pyrexia disappeared.<sup>4</sup>

**Case 8.**—A man, aged 45, suffered from myocarditis and emphysema; removal of eleven grossly septic teeth was followed by great improvement in health. Later six more were removed, and now, nine months after the extractions, he is able to walk two to three miles without discomfort, whereas formerly great discomfort followed after a mile. (Dr. Keith Tucker, Margate.)

**Case 9.**—Eight years ago a man began to have pain and swelling of the right hand, threatening later to incapacitate him from work. One tooth was removed, causing an exacerbation. X rays showed many apical abscesses. The infected teeth were removed, with the result that the condition cleared up entirely. (Mr. Fowler Ward, Ipswich.)

#### Signs of Infection.

The determination as to whether a tooth is dead is usually not difficult, as the tooth generally takes on a bluish-black colour. The diagnosis of infection, on the other hand, may be very difficult; the view that the live tooth may be infected further complicates matters. The most important clinical sign is tenderness on clinching the jaws and on percussion. This tenderness is well recognized by the patient, and is quite unlike that which results from "cold." The presence of tenderness in a dead tooth should

be regarded as sufficient reason for extraction; a radiograph sometimes shows nothing abnormal. In some cases the tongue will be found furred opposite an infected tooth.

A radiogram is invaluable in most cases. The first evidence of infection is a thickening of the periodontal membrane, visible in the film as an increase in the dark line round the tooth. As the condition proceeds one of two things happens—either (a) the pus may escape by passing between the tooth and the bone, causing a further increase in thickness of this line, usually on one side; or (b) if exit is impossible, a crescentic area of rarefaction appears, the tip of the root forming the concavity of the crescent. In either of these cases, but especially in the latter, actual absorption of the root may occur if the organisms are very numerous or virulent; in other cases the root appears bulbous owing to deposit of cementum; the organisms being of lower virulence.

It is of the utmost importance to examine the whole length of the jaws when a dental focus of infection is suspected, as only in this way can remnants, cysts, and abscesses be revealed. One cause of persistence of symptoms is residual infection of the socket; in such cases the socket outline may be apparent years after clinical healing has occurred. It must be clearly understood that a radiogram only shows involvement of the alveolus with any certainty; a tooth may be dead and infected and show nothing on the skiagram, as in Case 1.

#### Causes of Death and Infection of Teeth.<sup>5</sup>

1. Failure to remove all carious dentine at the time of filling allows caries to go on until finally the pulp is reached and death of the tooth occurs.

2. Synthetic fillings such as are used for front teeth may kill the pulp, owing to their phosphoric acid content, unless they have a cement lining.

3. Paraform and other disinfectant dressings may kill the pulp, which subsequently may become infected by the blood stream.

4. "Capping" the pulp is a frequent cause of ultimate death of a tooth.

5. Trauma to a tooth or the alveolus in the vicinity may interfere with the circulation of the pulp.

6. Operations on the antrum may implicate the superior dental nerves and vessels.

7. Local anaesthetics containing adrenaline render the tooth painless, so giving no warning of pulp exposure. Pain in this case develops immediately the effect of the drug has worn off.

8. Large metal fillings near the pulp may cause irritation and death of teeth, but these again are nearly always painful from the time of filling.

A devitalized tooth, in which the pulp has been replaced by gutta-percha, may function perfectly for many years. It is advisable to have it x-rayed at intervals for apical rarefaction; if this is present the tooth must be redressed until sterile and then refilled, or, better, extracted on the first evidence of infection.

#### Bacteriology.<sup>2</sup>

Examination for the micro-organism present at the apex of the tooth is difficult owing to the flooding of the socket with saliva due to the partial vacuum created by extraction. Before this is done the gum should be painted with absolute alcohol; iodine is contraindicated, since traces tend to adhere to the tooth and inhibit growth in culture. Immediate culture of the blood as it wells up is the surest way of discovering the bacteria responsible. The commonest organism found is the *Streptococcus salivarius*, but in acute abscess *Streptococcus haemolyticus* is frequent. If immediate culture is impossible, it is futile to place the tooth loose in a test tube, since contamination is inevitable. It should be embedded in the stopper of a wide-mouthed vessel. To examine the pulp the tooth is washed with alcohol, dried, then fractured, and its contents cultured.

#### Pathology.

In an infected tooth the necrotic nervous and vascular tissue forms an ideal pabulum for micro-organisms. In untreated caries the toxins and pus may pass into the mouth by way of the decay. In a filled tooth this exit is closed, so they proceed down the apical canals into the

bone, from which they may then pass into the mouth between the tooth and the bone, but in the greater number of cases the pus lies pent up in the apex, forming an abscess. Here in the sinusoids of the marrow it is free to exert a toxic influence on the whole body, as is shown by the anaemia which is so common in these cases. Apparently the relatively avascular tissues, such as fibrous tissue and synovial membrane, are the usual sites of election for local manifestations. The pulp chamber contains a bead of pus; any increase in the number or virulence of the bacteria causes increased pressure, which results in toxins and pus being squirted down into the bone. Natural resolution, which can occur in bone, cannot take place here, owing to the fact that the walls cannot collapse and no new tissue is available to fill the pulp cavity. Rarely, however, calcification occurs.

As with other streptococcal infections, once a patient has been attacked recurrences are very liable to occur, either from residual infection or from the subsequent infection of other teeth (Cases 1, 2, 6, and 8).

It is not yet possible to give a complete list of the diseases caused by infected teeth. Among those given are fibromyositis, arthritis, and lymphangitis. To these may be added others of a "rheumatic" nature, and possibly Dupuytren's contracture. It must not be thought that every case will clear up on removal of the infective focus; the condition may only be diagnosed when the disease is advanced, and then even its arrest may be problematical.

Sir William Willcox<sup>3</sup> states that the disabilities responsible for one-sixth of the days lost in the industrial world come under the category "rheumatic." In 100 consecutive cases of this nature he found the teeth to be responsible in 72. He writes:

"The eradication of the primary focus in early cases of arthritis has, in my experience, been followed by cessation of active inflammatory changes of the infected joints. Where bony changes have occurred, or other destruction of the joint, it cannot be expected that removal of the focus of infection will rectify these. When active inflammation of the joint has ceased treatment for restoration of movement will be followed by real improvement."

Much has been written on the areas of rarefaction seen in skiagrams of the teeth, and Weston Price has brought forward evidence that there are granulomata shutting off the toxins and bacteria from the general circulation. This may be so; I have heard of a man with six such areas who is in perfect health. Surely, however, there must be a grave potential danger of the resistance of this granulation tissue becoming lowered from time to time and allowing toxins and bacteria to escape.

Important advances might be made if all suspicious teeth found at necropsies of patients suffering from the diseases mentioned in this article, and others of obscure origin, were extracted and cultures made of their contents.

#### Summary.

1. A tooth may die painlessly before or after filling; infection readily occurs, and such a tooth may be the focus of autogenous infection.
2. The condition may be very much more serious than pyorrhoea alveolaris.
3. A positive radiogram indicates apical infection, but a negative one does not signify absence of disease of the pulp.
4. Continuance of symptoms after extraction, or in edentulous jaws, may be due to tooth remnants such as fragments of roots, abscesses, and cysts.
5. Special precautions are necessary at the time of extraction if bacteriological investigation is attempted.
6. The commonest diseases caused by dead and infected teeth are those termed rheumatic—namely, fibromyositis, synovitis, and arthritis.

It is a pleasure to acknowledge the help I have received from a symposium on this subject held at the Post-Graduate Hostel. Especially would I like to mention the contributions of Mr. Doubleday, Mr. Sprawson, and Dr. Human on the dental aspect, and of Dr. Cauti on the bacteriological investigations.

## FRACTURE OF THE NAVICULAR.

BY

K. PATERSON BROWN, M.B., F.R.C.S. Ed.,  
ASSISTANT SURGEON, ROYAL INFIRMARY, EDINBURGH.

So many patients are seen suffering from a persistent painful disability of the wrist following an unrecognized fracture of the navicular (Fig. 1) that it is important that the symptoms of this lesion be more widely known. These symptoms are characteristic, the treatment is simple, and the results extremely satisfactory if the patient is dealt with soon after the fracture occurs.

FIG. 1.—Radiogram of the carpus taken two years after the injury, showing, A, the two ununited fragments of the navicular. There are definite osseous changes present.

No attempt is made in this paper to consider every aspect of the subject—this has been done already by Todd.<sup>1</sup> My purpose is rather to accentuate the clinical features of the condition which are of diagnostic importance.

Fracture of the scaphoid bone (os naviculare) is by no means an uncommon lesion. In the past two years I have seen forty-six examples of the condition, but unfortunately the majority were late cases. These patients come to hospital complaining of persistent pain and stiffness in the wrist and inability to carry out their work efficiently. The history usually is that months or years previously the patient had fallen and injured the wrist. Either it was treated as a simple sprain or he paid no attention to it at the time, but the wrist never fully recovered, and was a continual source of trouble. If patients are to be spared a disability such as this it is essential that the fracture from which they suffer be diagnosed at once, and as the symptoms are so definite and characteristic, provided that this lesion be kept in mind, there should be little reason for its escaping notice.

The mechanism of injury is usually a fall on the outstretched hand, very similar to that which produces a

FIG. 2.—Case of recent fracture of the navicular, showing the dorso-radial swelling. Note that the swelling does not extend to the ulnar side of the wrist.

Colles's fracture. Less commonly the fracture results from the back-fire of a motor car. On examination of the wrist no gross deformity is noticed, but a very definite oedematous swelling is seen, situated on its dorso-radial aspect and extending into the anatomical snuff-box, with the result that the tendons bounding it no longer stand out prominently on extension of the thumb (Figs. 2 and 3). The swelling does not extend to the ulnar side of the wrist. Palpation reveals normal bony points, but there are two points of marked tenderness—one over the dorsum of the navicular, immediately below the line of the wrist-joint, and the other in the anatomical snuff-box, immediately below the styloid process of the radius. Pain at the site

of fracture may also be elicited by Vaughan's knuckle percussion test, which is described by Todd.

"The metacarpal joints are all flexed to a right angle, or if possible the patient is made to clench the fist; he is then told to keep his eyes shut, whilst the surgeon taps the knuckles smartly, one after another. If the fracture of the scaphoid is present sharp pain will be elicited when the head of the second metacarpal is struck, but not when any of the others is struck."

I have not found this sign of great value in diagnosis. In some cases it is not present, and in others it would appear to be present although no fracture is seen on x-ray examination.

The movements of the wrist, both in flexion and extension, are markedly limited, and the latter movement causes pain referred to the dorsal aspect of the navicular. Pain on flexion is rarely localized to a definite point.

The clinical features may be summarized as follows:

1. Swelling on the dorso-radial aspect of the wrist.
2. Obliteration of the tendons bounding the anatomical snuff-box.
3. Tenderness over the dorsum of the navicular.
4. Tenderness at the base of the snuff-box.
5. Limitation of flexion and extension of the wrist, the latter causing pain over the site of fracture.

While these symptoms are always prominent in recent cases they persist in untreated cases for long periods. I have recently seen a patient who had had an untreated fracture of the navicular for two years, and at the end of that period, when he came to hospital, he still showed all the characteristic signs which have been described.

I would stress the fact that diagnosis can be established without an x-ray examination, but, when available, plates should be taken to confirm the diagnosis. It is of the utmost importance that the skiagram be taken with the hand in marked ulnar deviation, for only in this position will all fractures of the navicular be detected.

FIG. 3.—Note the swelling in the anatomical snuff-box with masking of the extensor and abductor tendons.

FIG. 4.—Photograph taken five weeks after a fracture of the navicular, which had been treated in a plaster case. The patient was entirely free from pain, and full dorsiflexion was possible.

#### TREATMENT.

Immobilization is the keynote to success in the treatment of fracture of the navicular. The value of active movement in upper limb fractures is widely recognized, but the number of patients who suffer from a chronic disability following what has been erroneously diagnosed "sprained wrist," and treated by active movement, is sufficient proof that in this type of fracture, at least, it is not to be recommended. When the patient is seen

early the following treatment has given excellent results. A plaster case is applied to the forearm, wrist, and hand, the wrist being dorsiflexed, and the fingers and thumb maintained in the position of normal grip. In most cases it is necessary to give an anaesthetic to enable sufficient dorsiflexion to be obtained. The parts are immobilized in this

plaster for a period of three weeks, but at the end of a fortnight the upper half of the plaster is removed to allow of massage. At the end of the third week the plaster is discarded and free movement encouraged. All the patients who have been treated in this way have obtained perfect results, both as regards movement and freedom from pain (Fig. 4).

When the patient is not seen until a month or two have elapsed immobilization has not proved of value. In some of these cases the proximal fragment has been removed by operation, but the results are not very satisfactory, and equally good results have been obtained by a prolonged course of massage, together with exercises for the wrist and hot and cold douching of the part. In my experience, however, the vast majority of these patients are left with a chronic disability, pain and stiffness in the wrist, and with a marked tendency for osteo-arthritic changes to occur (Fig. 1).

## TWO CASES OF ACUTE YELLOW ATROPHY OF THE LIVER FOLLOWING ADMINISTRATION OF ATOPHAN.

BY

L. J. A. LOEWENTHAL, M.B., Ch.B.,

CLINICAL ASSISTANT, SKIN DEPARTMENT, LIVERPOOL ROYAL INFIRMARY;

W. A. MACKAY, M.D.,

HONORARY SURGEON, SOUTHPORT INFIRMARY;

AND

E. CRONIN LOWE, M.B.E., M.B., B.S.,

HONORARY PATHOLOGIST, SOUTHPORT INFIRMARY.

IN 1922 Schroeder<sup>1</sup> first drew attention to the toxic properties of the drug variously known as phenylethynonine acid, eincophen, quinophan, atophan, agotan, and phenoquin. His seventeen cases—chiefly of mild poisoning—consisted of headache, gastro-intestinal disturbances, and transient jaundice; while Worster-Drought<sup>2</sup> a year later reported a similar case. Following a communication from Langdon-Brown<sup>3</sup> in 1926, a dozen fatalities were reported by Evans,<sup>4</sup> Glover,<sup>5</sup> Wilcox,<sup>6</sup> and Wells.<sup>7</sup>

In his presidential address to the Section of Therapeutics of the Royal Society of Medicine Graham<sup>8</sup> emphasized the fact that every fatal case recorded was the result of uninterrupted use of this compound for a more or less lengthy period. Individual susceptibility plays a certain

part in determining the production of poisoning, as may also previous hepatic derangement, but it is noteworthy that there is no record, except in our second case, of any untoward result of this form of therapy where the drug is given in the correct manner. By this is meant its administration for periods of not longer than four days with intervals of not less than four days, as advised by Graham. This method brings about the maximum excretion of uric acid; the extension of the drug beyond these bounds, therefore, is not only therapeutically useless, but may be positively harmful.

The following are notes of the authors' two cases:

#### CASE I.

*Read by L. J. A. L. before the Liverpool Medical Institution on February 23rd, 1928.*

E. H., aged 55, had suffered from rheumatoid arthritis for many years. In July, 1927, on the advice of a neighbour, she began taking atophan at the rate of three 7½-grain tablets daily and without intermission. During the second week of January, 1928, she developed mild jaundice, apparently without any other symptoms. The final catastrophe occurred suddenly. The jaundice became more pronounced, on January 20th coma followed delirium, and she died on the following day.

The faeces had retained their normal colour throughout, and on this account a diagnosis of "acute yellow atrophy of the liver" was made. In view of the self-administration of atophan a coroner's inquest was held and a post-mortem examination performed.

*Pathological Report.*

(By the courtesy of Dr. W. Howel Evans of the University of Liverpool.)

**Macroscopically.**—The liver was the typical yellow-ochre colour, with small reddish cell areas. It weighed about 19 ounces, and resembled in consistency a fluid jelly contained in a thin capsule. The gall-bladder was normal, and contained a small quantity of bile. There were no gall-stones present.

**Microscopically.**—Sections showed a moderate degree of multilobular cirrhosis, which probably antedated the acute yellow atrophy. The great majority of the liver cells were completely necrotic; some areas showed fatty degeneration. There seemed to be practically no attempt at compensatory regeneration. The picture is that of almost complete necrosis, with the addition of the areas of fibrous tissue and the round-celled infiltration due to the multilobular cirrhosis.

## CASE II.

Reported by W. A. M.

"Mrs. R., aged 55. Previous history—nothing pertinent. On April 28th, 1927, the urine had been tested, and gave specific gravity 1010, reaction acid, no sugar or albumin. In May, 1923, she had sustained a fracture of the skull, with wound (compound fissured fracture). In the second week of December, 1927, she was ordered, for neuritic pains, atophan (7½ grains) three times a day for three days a week, and to take each morning a teaspoonful of sodium bicarbonate. According to her daughter's evidence at the inquest she never exceeded the dose, and ceased taking the drug about the end of January, 1928—five weeks before death. This was about a fortnight before the onset of jaundice.

On February 15th I found her jaundiced to a slight degree. She was put to bed, but became deeply jaundiced, and evidently was going downhill. There was some tenderness over the gall-bladder, and, owing to the uncertainty of the diagnosis, exploration was determined upon. A small cirrhotic-looking liver was found, but no dilatation of the ducts. She died within twenty-four hours on March 5th, 1928.

The urine had contained bile pigment. The faeces could not be got free from urine, and the examination of them gave equivocal results as regards the evidence of bile. *Post mortem.* a biphasic van den Bergh reaction was obtained on the blood. No obvious cause of the atrophy was found, and it was thought better to report the suspicion to the coroner, who held an inquest.

The extreme quantity she could have taken is 540 grains spread over eight weeks, and four days' interval followed each 67½ grains. At first she told her family that the drug was doing her good; later she had expressed a doubt.

*Post-mortem Report (E. C. L.).*

**Macroscopically.**—The liver was considerably smaller than normal, weighing about 26 ounces; it was soft in consistency, its capsule showing typical shrinkage. The cut surface was of the typical yellow-ochre colour and studded with small reddish areas. The gall-bladder and bile ducts were normal and patent. No gall-stones or cholecystitis were present. The pancreas was normal in size and consistency. The spleen was not enlarged, but rather softer in consistency than normal. The kidneys were normal in size, but somewhat soft in consistency.

**Microscopically.**—Liver sections showed marked necrosis of the hepatic tissue, interspersed with round-celled infiltration, without the development of any multilobular cirrhotic changes, the picture being typical of acute yellow atrophy. Sections of the spleen and pancreas showed no abnormal findings. Sections of the kidneys showed marked parenchymatous degeneration of the tubular epithelium, and suggest a considerable amount of subacute nephritis.

*Conclusions.*

1. Poisoning by phenylethionine acid and its congeners is a condition which the medical practitioner should always bear in mind.

2. There may be no premonitory symptoms, although urticaria, albuminuria, gastro-intestinal disturbances, and transient jaundice have been noted. Acute yellow atrophy ushers in the fatal termination.

3. For the present we would suggest that the presence of albuminuria or any evidence of nephritis should be considered as a contraindication for the administration of this drug.

4. The slightest sign of intolerance, such as nausea or loss of appetite, should be an indication for the immediate stoppage of administration of the drug.

5. The estimation of a van den Bergh reaction and icteric index of the patient's serum will probably give the earliest evidence of any pathological effect upon the liver cells, and present the opportunity for omitting treatment,

long before any evidence of clinical jaundice could be observed.

6. Even if administered in the correct intermittent manner phenylethionine acid or any of its congeners may be a dangerous drug. The authors feel that its indiscriminate use is very undesirable.

## Memoranda:

## MEDICAL, SURGICAL, OBSTETRICAL.

## GAS GANGRENE OF SIGMOID.

I venture to think that the following case, resulting in death from toxæmia in twelve hours, must be fortunately of rare occurrence.

On February 27th, at 3.15 a.m., I was called to see a man, aged 51, with violent abdominal pain which had lasted about an hour. He had vomited twice, and had passed a little blood and mucus. The pain had begun in the right iliac fossa, and had become generalized. He was a healthy man, and looked less than his age. There was no history of any abdominal symptoms whatsoever, and of no illness except "rheumatism."

**Condition on Examination.**—He appeared to be very ill and was in obvious agony, though not collapsed. The temperature was 98° F., and the pulse 88. The tongue was furred, brown, and very dry. The abdomen moved on respiration; it was somewhat distended and extremely resistant, though there was no board-like rigidity. The tenderness was marked and universal. No assistance was given by a rectal examination.

**Diagnosis.**—This was difficult to fit in with any of the ordinary causes of an "acute abdomen" in a man of his age. It was decided to operate on the assumption that volvulus was present, and a quarter of a grain of morphine was given.

At 4.30 a.m. the pulse was 100 and the temperature was 100° F. There had been no more vomiting, but the pain was quite unrelieved.

**Operation.**—After a second injection of a quarter of a grain of morphine and 1/100 grain of atropine, the right rectus was displaced outwards below the umbilicus; free peritoneal fluid welled up on opening the cavity. The appendix was found to be normal, the gall-bladder was blue and apparently normal; the intestines were not unduly distended, and there was nothing to suggest an obstruction; there was no sign of duodenal or stomach contents, nor was any ulcer felt. There was no question of acute pancreatitis or of diverticulitis. The only abnormality I could find was in the lowest part of the sigmoid, where it passed into the rectum; this was rather swollen, oedematous, and stained by a few purple petechiae near the mesenteric border. I was frankly puzzled, since I hardly thought a lesion so low down, and so unfamiliar as a cause of an abdominal catastrophe, could account for the acute onset and extreme illness of the patient. His general condition was good and the pulse had hardly risen (120). Mr. Arthur Cooke also carefully examined the abdominal cavity and found everything normal except the sigmoid. He had never seen such a case, but hazarded an opinion of a *B. welchii* infection of the affected loop, and 10 c.c.m. of gas gangrene serum was injected immediately. At the end of the operation the pulse rate was 100, and a rectal saline was given. At 9 a.m. the pulse was still only 100. The tongue was more moist, and his colour was better, but the agony was unrelieved. Morphine (1/4 grain) was given. At 12 noon the pulse had risen to 140; he was flushed and there was cyanosis. The breathing was rapid. The patient was evidently still in terrible pain; he had not vomited since the operation. The abdomen was somewhat distended. Another quarter of a grain of morphine was given. At 2.15 p.m. the patient had become cyanosed and grey; he was completely comatose and pulseless, and died a quarter of an hour later.

**Post-mortem Findings.**—Permission for a limited necropsy was obtained, and at 9 p.m., with Dr. H. E. Nourse, I explored the abdomen through the original incision extended upwards. The *post-mortem* changes generally were very marked for the short time since death, and the odour on reopening the distended suture line was appalling. There was mucous exudate, and the changes in the rectum to complete gangrene for about six inches reflected of the peritoneum. There was no bubbles of gas were observed below the peritoneal coat. Elsewhere the abdomen was quite normal.

I sent some of the fluid and five inches of the gut to the Bonnett Laboratory; the following is a summary of Dr. C. H. Whittle's pathological report.

1. *Erudate.*—Large numbers of Gram-positive capsulated bacilli were found in films. Culture: (a) aerobic—streptococci and *Staphylococcus albus*; (b) anaerobic—a bacillus of the *B. welchii* group.

2. *Sections of Gut.*—There was intense congestion and gangrene of the whole wall and bleeding into the lumen. The wall was

packed with *B. welchii*. The blood vessels of the mesocolon of the affected part were thrombosed; the vessels showed no sign of any previous disease.

3. *Animal Inoculation*.—A guinea-pig inoculated intramuscularly and subcutaneously with broth cultures died within forty-eight hours from gas gangrene. The organism was highly pathogenic.

It is difficult to assign a cause for a primary thrombosis, because Mr. Cooke and I are both satisfied that there could have been no volvulus in the relatively immobile loop.

If, alternatively, it is assumed that the thrombosis was secondary to the intensity of the inflammatory process (which must have started in the mucous membrane), the reason for the selection of the sigmoid for attack in a perfectly healthy subject has still to be explained.

The case was as tragic as its origin was obscure.

Cambridge.

R. SALISBURY WOODS, M.D., F.R.C.S.

### TREATMENT OF VARICOSE VEINS BY INJECTIONS.

IN the course of a series of treatments for varicose veins of the lower extremities my attention was drawn to the fact that the size of the veins varied considerably with the act of respiration, and it occurred to me to make use of this when injecting them. If a patient, either standing or lying down, is asked to take a deep breath, the veins will be seen to dilate on inspiration and to contract on expiration. This phenomenon is best seen in markedly dilated veins on the inner side of the thigh, especially over the great saphenous vein; it occurs in a lesser or almost imperceptible degree in the veins of the leg. It exists, however, in all cases.

Two requirements must be fulfilled to obtain satisfactory results in treating varicose veins by sclerosing injections: (1) the injected fluid must not be too diluted by the amount of blood in the vein, and (2) the fluid must come in as direct contact with the endothelium of the vein as possible. For these reasons the injections must be given with the patient lying in certain positions which tend to empty the veins as much as possible of their blood; taking advantage of the changes due to respiration will, I believe, also help in this.

The site for injection having been purified, the patient should be asked to take a very deep breath; while he is doing so the needle is inserted. He is then asked to breathe out very slowly, and the solution is injected while he is doing this. In this way the needle will be inserted when the vein is distended, and the injection will be given when it is almost empty. In making use of respiration and posture I have found that a smaller quantity of the sclerosing solution will bring about the same end-results, since there is less blood to dilute the fluid, and also the walls of the vein are in closer contact with the injection. After all injections the patient should lie down for ten minutes, and during that time breathe slowly and lightly. It will be noticed that when a vein has been successfully treated its size is no longer affected by respiration.

I have ventured to record these details since I have been unable to find any reference regarding the effects of respiration in connexion with varicose veins, and think it may be of interest and worthy of further study.

London, S.W.

T. HENRY TREVES BARBER, M.D.

### LARYNGEAL MYXOEDEMA.

THE fact that the diagnosis, and therefore the correct treatment, was missed by general practitioner, physician, and laryngologist alike in three successive cases of laryngeal myxoedema, suggests that a note may be useful.

The first case was that of a surgeon, aged 65. He had always had good health, although there was, on rare occasions, slight albuminuria. He complained that when he tried to sing all he could get instead of a clear note was a grunt. There was some swelling about the eyes; his voice was hoarse; there was pronounced oedema, red, glazy, of the mucosa of the back and sides of the larynx and of the ventricular bands. On a grain of thyroid extract twice daily he quickly got rid of the oedema of his face and larynx, regained his voice, and vigour, and has continued an active professional life for the last four years. On inquiry it was found that his sister died of myxoedema.

The next case was that of a Salvation Army officer, aged 60, who found open-air speaking a difficulty. The symptoms in this case were not pronounced as in the previous one; the vocal cords were sound, but there was some beefiness of the rest of the larynx, thinning of the eyebrows, and clear waxy skin with scattered telangiectases. The whole aspect suggested hypothyroidism, and the diagnosis was made instantly on inspection by my assistant. Thyroid extract cleared up the case.

The third case is the most interesting. A lady of 70 came to me in July complaining of laryngitis, for which she had been sent home from the coast, although she had been there only two days and the "laryngitis" had lasted six months; the voice, indeed, was hoarse, the mucosa above the glottis, and especially on the back of the larynx, was beefy red. Moreover, she had marked exophthalmos, and gave a history of severe Graves's disease when she was 30, which had disappeared by the time she was 40. Viewed across the room, however, her face looked thick; and, when asked about it, she used the suggestive expression, "When I wash my face it fills my hands." Under a fortnight's treatment with thyroid extract her symptoms disappeared—except the exophthalmos. This was a case of hyperthyroidism passing during forty years through fibrosis into the "hypo" stage, but leaving the exophthalmos for witness of the hyper. one.

The cause of error was simple and the same in all—distraction from the general appearance and symptoms by the patient's complaint of the laryngeal condition. There was some excuse in each case: in the first because the patient was a man, and so familiar to his colleagues that they were thrown off their guard; in the second because the symptoms were slight; in the third because of the exophthalmos. If myxoedema is not suggested to the observer's mind by the patient's appearance and voice the moment the latter enters the consulting room the diagnosis is apt to be missed. The laryngeal picture, however, is unmistakable. The back of the larynx looks like a beefy red shield and throws itself at one's eye. Certainly the pale anæmic appearance of some textbooks was not exemplified in these cases. A "laryngitis" that has lasted for months and leaves the true cords practically unchanged in appearance is presumably myxoedema.

JAMES ADAM, M.D., F.R.F.P.S. GLAS.,  
Surgeon for Diseases of Ear, Nose, and Throat,  
Glasgow Parish Council.

## Reports of Societies.

### THE ETIOLOGY OF ALCOHOLISM.

THE Section of Psychiatry of the Royal Society of Medicine joined with the British Psychological Society on March 29th for a discussion on the etiology of alcoholism. Dr. R. LANGDON-DOWN, president of the Section, was in the chair.

Dr. BERNARD HART, opening, said that to the question, "Why do certain people take alcohol to excess?" many answers had been returned. Leaving aside such facile explanations as that alcoholism was a vice or a disease—explanations which added nothing to knowledge—theories had been put forward emphasizing the part played by heredity, by the mechanism of habit, and by the response to stresses and strains in the mental organism. Psychological theories of recent origin tended to dominate the field, and the other factors were now in some danger of being unduly minimized. In the modern psychological approach to the subject it was held that the forces which drove men to take alcohol to excess were, in some measure, at least, identical with those which impelled men to take it at all, and it would seem that the causation of alcoholism must be sought for by inquiry into the effects of alcohol. Stockert had divided such effects into psychomotor stimulation, coupled with euphoric affective tone, and, secondly, a "dulling" process extending to paralysis. The speaker thought that these groups might usefully be employed as a basis for further amplification. Possibly the euphoria was only to be explained in chemical terms, or it might be directly produced only in part, and be in some measure the secondary result of the removal of inhibitions and the consequent release of impulses. With regard to the "dulling" process, in general it might be said that psychoanalysts accepted the view that alcohol was taken in order to achieve a psychological aim, which consisted partly in the assuaging of conflict and partly in the attainment of freedom of expression for repressed forces. The euphoric

affective tone, the submerging of conflicts, the cloaking of reality, the release of impulses, were all possible ends, and it might be expected that in the wide range constituted by these various ends would be found the psychological factors responsible for alcoholism, though it was a debatable question how far alcohol was to be regarded as an aim and how far as a price to be paid to achieve some other end. The psychological aims, however, although important, did not exhaust the problem. The craving which formed an essential feature of chronic alcoholism was not capable of satisfactory explanation in psychological terms, and the processes involved were probably best understood by employing chemical conceptions. Altogether, the various psychological aims, the craving, and the mechanism of habit might be said to constitute the factors immediately responsible for the development of alcoholism. The question arose whether these exciting causes acted on each and every individual, or whether certain persons were predisposed to their action, either by hereditary constitution or previous history. To the earlier authorities, as well as to a number of later investigators, heredity was the factor of predominant importance, although it had been conceived to act in many different ways. After discussing various theories which had been put forward, Dr. Hart said that it was apparent that there was a wide range of opinion as to the relative importance to be assigned to the various contributory factors to the etiology of alcoholism. Hereditary constitution, prior psychopathic conditions, conscious or unconscious "urges," the striving to achieve relief from conflict, the release of inhibited impulses, habit, custom, tradition—all were differently estimated by various authorities. On the one hand, there was such a statement as that given by J. T. MacCurdy, in discussing the etiological factors in alcoholic psychoses (*British Medical Journal*, 1922, vol. ii, p. 204), that "the alcoholic is, before he even touches a drop, an abnormal person," and on the other hand, there were those who maintained that alcoholism might arise in the normal person untroubled by internal conflicts or "urges," solely as the result of fortuitous environmental circumstances working upon the mechanism of habit. Stockert, who took a wide view of the problem, concluded that alcoholism might arise in many different soils and for many different reasons; he divided alcoholics into convivial drinkers and those who took alcohol as a drug, and subdivided the latter group into weaklings, who drank merely because it was the easiest way to obtain pleasant sensations, and psychopaths, asocial repressed personalities, who could only adapt to environment with the help of alcohol, or could only in this way substitute day-dreams for reality. Such a classification was of a rough-and-ready character, certainly incomplete, but it served to indicate the many-sided nature of the problem. The solution was not to be found in any single or specific mechanism. Alcohol might serve one or more of several ends, and various types of individuals, on account of their hereditary constitution or their previous history, might be more or less likely to avail themselves of alcohol as a means of securing these ends, and so engender processes in which presently habit would play its fixing part.

Dr. EDWARD GLOVER agreed that not all psychopathologists were at one on the etiology of alcoholism. He himself urged that three main etiological factors had to be considered in relation to this condition—namely, the partial fixation of the libido at certain levels, the constant tendency to regress to a narcissistic ego-organism which automatically set primitive mechanisms into action, and disorders of primitive conscience, which lead to fruitless exploitation of this mechanism of projection. He noted the resemblance between alcoholic lability and manic-depressive insanity, and suggested that some forms of alcoholism might be called artificial manic-depressive states, though the manic depressive had a more severe "oral fixation of libido," his super-ego was more disordered, and his sadism completely inverted. On the other hand, with more primitive narcissistic regression and more disintegration of the super-ego, the picture became one of paranoia. The speaker argued in favour of there being a close relation between alcoholism and perversion, suggesting even that alcohol might be chosen as a means of short-circuiting

sexuality and releasing the pressure of repression. Although alcohol brought out important perverse sexual tendencies it might be said that it had a function as a "surrogate" of component sexuality. Alcoholism itself might be described as a pseudo-perversion. Finally, its close relation to pseudo-sexual impotence was a reminder of the fundamental significance of "castration anxiety." Alcohol, said the speaker, owed much of its attraction to the fact that it was primarily well adapted to overcome this anxiety, although in the long run it defeated its own end by bringing about impotence and death.

Dr. EDWARD MAROTNER said that it was probable that the great majority of normal drinkers took alcohol because, although it might be bad, it made them "feel good." He believed that of the youths who indulged unduly in alcohol on Boat Race night only a small percentage did so with the idea of drowning world weariness or a secret sorrow. If he was wrong in this, psychoanalysts should be retained at Vine Street and these youths be submitted to them instead of being brought before a magistrate, who crudely fined them forty shillings! Alcohol had been called the "anaesthetic of the poor," though it seemed quite popular among the well-to-do also, and he doubted whether the poor regarded it in so negative a light. Most alcoholism which sought negative effects was more than alcoholism, but there was much alcoholism which at first was positive—pleasure seeking or the "doctor's orders" type—and subsequently became hardened by habit. To ask whether the factors which induced men to drink were psychological or physico-chemical was not to present a true antithesis. Was euphoria the result of stimulation or of decontrol, with, in the latter case, necessary impairment of a higher level? Dr. Hart seemed to have preferred the idea of stimulation, which was certainly the more cheerful and, the present speaker thought, sound, but it did not appeal to English scientists—witness the report of the committee of the Medical Research Council on alcohol in 1923. Incidentally he thought it rather cynical for such a body to assume that something which resulted in a decrease of receptivity and cast a veil over reality was almost universally bound to enhance cheerfulness. It was possible that the euphoria was due to the fact that alcohol was taken with a lively expectation that it would produce euphoria, and it would be interesting to learn whether any experiments had been done to show whether euphoria followed upon the taking of alcohol in ignorance. The speaker went on to remark on the slow decrease in the consumption of alcohol since the beginning of the century, and the very striking decrease during the ten years 1914 to 1923. During those ten years there was a fall in the consumption per head of about 50 per cent. This result must have been due, not to the sudden abstinence or disappearance of the comparatively small numbers of alcoholics, but to the cutting down of alcoholic consumption by the moderate drinker. Moderate drinking was not a subject, in the main, for individualized psychological study, but depended on such factors as social custom, cost of liquor, and facilities for obtaining it. The speaker thought there had been a decrease in the number of cases of alcoholic psychosis by about two-thirds after the war as compared with the pre-war period; alcoholic morbidity was reduced to about one-third of its pre-war prevalence. As for the idea that homosexuality had any predominant or specific relation to alcoholism, he asked if there was anybody of experience, who was not in other matters Freudian, who accepted this. If there were such cases he would expect to find that at some period they had shown unmistakable signs of overt homosexuality, or that this had figured in the content of delusions and hallucinations. He had been carefully through sixty cases of alcoholic psychosis at Maudsley during five years, and the proportion in which any overt homosexuality was evidenced was negligible—this in spite of the fact that the cases were, short of psycho-analysis, dealt with adequately.

Dr. H. CRICHTON MILLER declared that in the broadest sense alcohol might be said to be taken in order to modify the feeling tone. The numerous modifications of feeling tone which resulted from the ingestion of alcohol could be referred to two chief mechanisms—interruption in the continuity of the functioning of the central nervous system,

and a regressive change whereby the activity of the cortical centres was subordinated to thalamic control. Acquired inhibition succumbed to instinctive pressure, and conceptual thinking was submerged by perceptual activity. It might be presumed that these changes depended on two physical mechanisms, one largely and the other entirely hypothetical—namely, change in intracranial blood pressure, and alteration in functioning directly occasioned by alteration in the chemical constitution of the cerebro-spinal fluid. The modification of feeling tone or euphoria thus produced might be sought under many circumstances. In the first place, any effortless attainment of oblivion must necessarily constitute an alluring retreat from most forms of conflict. People were enabled to forget their past follies and future difficulties; in other words, a retreat from conceptual to perceptual ideation was frequently pleasant, if not desirable. The introverted found in alcohol a chemical solvent of those inhibitions that dammed up his self-expression, and the man with an inferiority sense felt himself 100 per cent. better when alcohol had blurred his discriminating capacity. The psychasthenic, with his constitutional intolerance of strain, physical or emotional, derived from alcohol a temporary rise in the threshold of consciousness. Similarly there were two groups whose demand for alcoholic euphoria was based upon physical states—one the hypopietic and the other the subthyroidic. Probably the factor of low blood pressure entered into a very high proportion of all cases of alcoholism, especially among women, the ill-nourished, and the toxic. That alcohol afforded satisfaction to many subthyroidics was notorious; presumably the mechanism was a general vaso-motor stimulation. On the other hand, hyperthyroidics did not tend to be steady drinkers. Another group was the sensorial type, who sought the modifications in sensory experience produced by alcohol. To this group belonged those who alternated alcoholism with excessive auto-erotism. The "rebels" should also be mentioned—those who drank because their fathers were rabid temperance reformers, just as the son of a fanatical Calvinist became a Roman Catholic and the son of a Tory Minister became a Fabian. In this group gold cures or injections of alkaloids reached the limit of absurdity. He also mentioned the group which showed an association between alcoholism and epilepsy, the "dual personality" group, and the manic-depressive group, this last resistant alike to analytical treatment, to forced abstinence, to medicinal cures, and to affective influences. In this group the alcoholic craving might be a feature either of the depressed or of the exalted phase, but not, in his experience, of both phases.

Professor GEORGE M. ROBERTSON agreed that no single formula could be adopted to explain the etiology of alcoholism; nor could there be one therapeutic method. In most cases a lowering of mental functioning by some process or other was involved, in consequence of which the mental powers were less able to encompass difficulties; it might be due either to a psychic or a somatic cause. In most cases there was conflict of some kind, and in addition temptation and the presence of facilities. He doubted whether there was craving for alcohol in the same sense as for morphine in the morphine addict. In the latter case there was probably a toxic chemical change in the blood, and he did not believe that the same thing occurred in alcoholism. Again, the sudden cessation of alcohol in the case of the alcoholic, while it might possibly produce delirium tremens, did not result in anything like the same damage as the sudden cessation of morphine in the case of the morphine addict.

Dr. W. H. B. STODDART quarrelled with the definition of alcoholism given by Dr. Hart—that it was the state of a person who took large quantities of alcohol—for he (Dr. Stoddart) maintained that a person might be an alcoholic before he had taken any large quantities. During the war he saw at least four cases of delirium tremens occurring in people who, previously to the restrictions on alcohol, had been quite moderate drinkers. During the restriction period, however, these people had attacks of anxiety as the time for the closing of public-houses drew near, and drank as much alcohol as they could obtain; all of them developed delirium tremens. The speaker therefore

regarded alcoholism as including the state of a person who believed that he could not do without alcohol; it was not necessary to take large quantities before becoming an alcoholic. He added that in the treatment of delirium tremens to cut off all alcohol sharply might be serious. Nowadays it was usual in this condition to give a little alcohol.

Dr. ALFRED CARVER (Birmingham) answered Dr. Mapother's question as to whether euphoria could be obtained without the patient knowing that he had imbibed alcohol. In certain manic-depressive cases some alcohol had to be given unknown to the patient; it was given with paraldehyde, which was so pungent as quite to disguise the alcoholic taste. The patient was told that it was medicine, but the euphoria was forthcoming as usual. Dr. Hart had stated that in ordinary recurrent attacks of alcoholism he did not think the craving arose before the taking of the first dose. The speaker's experience of cases was different. The craving most certainly arose before they had touched a drop.

Dr. T. A. ROSS said that craving for alcohol frequently arose in a person who was encountering difficulties, or some obstacle which was too much for him, or experiencing some strong emotion, thus differing from the craving for morphine, which had a physico-chemical basis. In his experience delirium tremens or other accident did not often result from the sudden cutting off of alcohol, but in the case of morphine addiction the drug could not be cut off suddenly.

Dr. ARTHUR HADFIELD thought that the majority of people who suffered from alcoholism—not of the social type, but of the drug type—were people of highly strung temperament. This introduced an heredity factor, because temperament was in most cases inherited, and there was also a physiological factor in which low blood pressure played a part. But the fundamental factor he believed to be regression—these were people with a fatal predisposition which prevented them from facing the difficulties of life, simply because they had never grown up.

Dr. M. P. LEAHY spoke of the good effect of suggestion in combating the fixed idea of the alcoholic that he must have alcohol; it depended, of course, on the non-resistance by the patient to the injection of the opposite idea.

Dr. J. D. ROLLESTON drew attention to the ancient and modern association of alcoholism and prostitution; the modern association was disclosed in the recent report of the committee of experts appointed by the League of Nations. There was also an alcoholism which might be described as of therapeutic origin. Some persons who were originally abstainers became chronic inebriates because they had been ordered by their doctors to take some alcohol.

Dr. J. BRANDER said that he had been a little alarmed to hear that evening of the multitude of abnormal psychological states which must be held to account for the habitual addiction to alcohol even in moderation. Was it really necessary to call in a psycho-analytical explanation of the "Frothblowers"? And would it not be necessary also to apply the same researches to the much-advertised effects of certain tonics and "sovereign remedies"?

## FEMALE SEX HORMONES.

At a meeting of the Section of Comparative Medicine of the Royal Society of Medicine, held on March 28th, with the president, Sir D'ANEX POWER, in the chair, several short papers were read, of which two had a general medical interest.

Dr. J. W. TREVAN spoke on recent advances in our knowledge of the female sex hormones. He said that now that there was a method of standardizing and isolating one of the female sex hormones great extension of knowledge was possible. Dealing with the fundamental problems of the differentiation of the sexes Dr. Trevan illustrated the essential features of the chromosomal difference, and went on to describe the freemartin, which was a calf with the external genetic pattern of the female, but internally like the male. This calf was always a twin, with anastomosis of the placental circulation with a twin male.

The testis developed in the male before the ovary in the female, and it was supposed that a hormone from the testis prevented the development of the corresponding female hormone in the freemartin. This was the first of the sex hormones. The next changes occurred at puberty, and it was especially the cyclic anatomical changes which had recently been studied, mostly in the rat. At oestrus in this animal there was not only a swelling of the external genitalia, but there was an actual change in the character of the vaginal secretion, whereby cornified epithelial cells almost completely replaced the leucocytes which were present in the dioestral period. There were corresponding, if not so easily detectable, changes in other animals. The first step towards finding out something about the cause of this phenomenon was the discovery that the hormone concerned could be obtained by a process of alcoholic extraction of the ovary in a certain way, and the biggest experimental step was made by Allen and Doisy in 1924, when they produced the characteristic changes in the vaginal secretion of the rat by the hormone they had obtained from the ovary. This it was proposed to call oestrin, and it could be obtained from the ovarian residuum in an amount of about 200 to 300 rat units per kilo. It could also be obtained from the follicular fluid and from the placenta, and, what was very surprising, also from the corpus luteum. The effect of injection of oestrin was to produce oestrus in rats, even if they had their ovaries previously removed. If a young rat was splayed its vagina remained as a solid cord of cells, but within twenty-four to forty-eight hours after the injection of one to two rat units of oestrin the vagina became a tube. Oestrin had been obtained from the ovaries of the sheep in the anoestral period, and this raised the question of why oestrus was a cyclical phenomenon. It had been suggested that it was due to the ripening of the follicles, but Parkes had destroyed follicular tissue in mice by means of x rays, and these animals went on having the cyclic phenomenon as before. The next problem was whether the corpus luteum was responsible, and recent work by the speaker suggested that the corpus luteum contained another sex hormone, which might be called anti-oestrin. This might explain the absence of the cyclic phenomenon during pregnancy, for the blood at this time contained very large amounts of oestrin. Finally, Dr. Trevan suggested the possibility of yet another hormone concerned with reproduction, and he also discussed the role of the anterior lobe of the pituitary in preventing the onset of puberty.

#### B.C.G. Vaccine.

Dr. H. J. PARISH described his work with B.C.G. (Bacille Calmette-Guérin) vaccine and guinea-pigs. This work had been undertaken by himself and Dr. C. C. Okell to confirm the work of Calmette on the prophylactic effect of B.C.G. vaccine in the tuberculous infection of guinea-pigs. He recalled briefly the preparation of the B.C.G. vaccine by Calmette over a period of thirteen years, and then described in detail one of the four series of experiments which had been made. Into each of a group of guinea-pigs 20 mg. of vaccine were injected intravenously, and after five to eight weeks 0.01 mg. of a virulent bovine tubercle bacillus strain was inoculated on to the eyeball. The average period of survival was thirty-five weeks, as compared with a control group of animals which had not received the B.C.G. vaccine, and which survived for an average period of twenty weeks. Of the vaccinated group six did not succumb, and at necropsy they showed no signs of tuberculosis. These might have escaped being infected at the time of inoculation, but even excluding these the period of survival was twenty-nine weeks, and still considerably longer than in the control group. The fact that there were six survivors in the vaccinated group was of great significance. The average increase in weight after infection was three times as great in the vaccinated as compared with the control animals. Dr. Parish concluded that B.C.G. vaccine does exercise a restraining influence on the development of tuberculosis. In none of the experiments had there been any evidence that the vaccine ever did any harm. Some guinea-pigs had been kept alive for a year after vaccination, and at necropsy there was no sign of tuberculosis.

#### ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

At a clinical meeting of the Aberdeen Medico-Chirurgical Society on March 1st, the president, Dr. THOMAS FRASER, in the chair, Mr. G. H. COLT showed a boy, aged 12 years, who had fallen down three steps and struck the left side of his abdomen. The boy felt sick, but did not vomit, and had been kept in bed. After a week an epigastric swelling appeared; it extended into the left loin, and there was an evening rise of temperature to 101° F. The swelling was apparently fluid, and its dullness merged into that of the spleen; the colon lay below it. The blood count and diastatic index were both normal. From the fourteenth to the twenty-first day there had been profuse bright haematuria, which had begun and ceased suddenly; no clots were passed. The size of the swelling had somewhat diminished since his admission on the twelfth day. No other symptoms had been noticed, and the temperature had not been raised. The quantities of urine passed and the urea percentages in the urine and blood were normal. The diagnosis lay between a pseudo-pancreatic cyst (Jordan Lloyd) and a renal cyst or haematoma. Dr. J. A. STEPHEN described the history of a case of difficult feeding in an infant where lactic acid milk and insulin and intraperitoneal salines were employed. The child weighed 5 lb. 6 oz. at birth, and during the first period of three and a half weeks on breast feeding the gain was only 1½ oz. For the next seven weeks it was given a supplementary feed of lactic acid milk four-hourly for three days; it was then weaned and fed on lactic acid milk. In four months the child gained only 1 lb., and yet it had made quite satisfactory progress at the end of one year. Dr. EDWARD WALKER exhibited a male child, aged 11 months, showing several of the stigmata of Mongolism. The skull was brachycephalic, but without marked occipital flattening. The features were small and high coloured. There was a slanting palpebral fissure downwards and outwards, a reversal of the common peculiarity which has been reported in otherwise typical Mongols. The nose was small and snubbed, and the tongue, which was large and broad, protruded from the mouth. The abdomen was large and tumid; the skin showed exaggerated mottling and was rather dry on the face, but not elsewhere. The thyroid gland was palpable. Mentally the child was bright and friendly, but it appeared to be stupid and was given to grimacing. A diagnosis of Mongolism associated with hypothyroidism was suggested, and thyroid extract was being administered as a therapeutic test. Mr. ALEXANDER MITCHELL showed a case of ectopia vesicae in a boy aged 5. There was no actual prolapse of the posterior wall of the bladder, but only a defect in the anterior wall, with a short penis and the lower half of the circumference of the urethra alone present. A plastic operation on the bladder was not considered advisable; it was hoped that the sphincter control of the rectum would improve when transplantation of the ureters into it could be effected. Mr. GEORGE S. DAVIDSON showed an x-ray film of a patient with a Naegele pelvis, who first came under his care in 1927. The point emphasized was that there ought to be much closer co-operation between the obstetrician and radiologist. Mr. WILLIAM ANDERSON showed a case of chronic pulmonary suppuration treated by cauterizing pneumectomy (Graham's method). Repeated aspirations had failed to locate pus. Four inches of the seventh, eighth, and ninth ribs posteriorly were resected. An indurated area was being excised when thick, foul pus escaped. The cavity was cauterized widely in all directions and packed, the skin wound being only partially closed. The convalescence was fairly smooth, but a sinus persisted at the patient's back. The wound was opened up and extended in an upward direction, the sixth rib being resected, the thickened area of the lung again thoroughly cauterized, and the wound packed. There was a free discharge of pus, and irrigation with flavine caused the sputum to be stained yellow. Five weeks later, however, the sinuses were practically dry, and soon after this it healed up. The patient returned to work as a street porter, which involved the dragging of a heavy trolley cart. His only complaint was slight breathlessness on extreme exertion, and the clubbing of the finger tips entirely disappeared.

## Rebifus.

### THE SOCIAL STRUCTURE OF ENGLAND AND WALES.

WHENEVER the time comes for organizing a national census those responsible for the work receive many suggestions for increasing the field of inquiry, and every year Government departments are invited or exhorted to obtain this or that new piece of statistical information. It not infrequently happens that those who make proposals are ill-acquainted both with the difficulties of the task they set and with the published results of similar inquiries. There is some excuse for this, because the mere mass of official publications is great, and it often happens that the precise meaning of some tabulation can only be grasped if the descriptive text—perhaps separated from the tables by a wide space—is carefully studied. In recent years a good deal has been done to smooth the path of the private inquirer by the Government itself—for example, in the admirable *Guide to Official Statistics*—and by organizations such as the League of Nations, in its handbooks of the official vital statistics of many important countries; but there was room for a treatise such as that of Professor A. M. Carr-Saunders and Dr. D. Caradog Jones,<sup>1</sup> which should illustrate the lessons to be learned from a study of the official, and some unofficial, data.

The authors first set out the salient facts as to the number, age, sex, marital condition, housing, geographical distribution, industrial, and occupational classification of the people. Next they consider the statistical measurement of social status, the numbers and nature of occupational associations, and other aggregates. The means of estimating national wealth and income are next considered; and then in turn education, ways of entering occupations, State provision against misfortune, taxation, charity, the measurement of poverty, the prevalence of crime. Finally, the distribution of "intelligence" and the differential birth rate are discussed and illustrated. The authors have treated their material in a lucid and objective way; the medical reader will find, in their discussion of the subject, matter of particular interest to him, little to criticize, and much which he should know, but perhaps does not know. Professor Carr-Saunders and Dr. Caradog Jones, having set out the facts as to the differential net fertilities of various social strata, abstain from rejoicing or bemoaning.

"The net results of differential rates of contribution," they remark, "may be favourable or unfavourable. It is at least possible that, even if they are unfavourable in respect of inborn intelligence, they may be favourable in respect of temperament and physique, and that, therefore, the general trend may not be in the direction of biological degeneration."

Similar caution is displayed in the introduction to the chapter on inborn qualities, although the authors seem to accept the view that the intelligence quotient is a measure of innate qualities; it might perhaps be remarked that the conclusion that "most of those tested are moderately gifted with intelligence" is a truism, having regard to the definition of an intelligence quotient, although, of course, the result that very high and very low quotients are about equally numerous is not a truism. It might perhaps have been an improvement had rather more space been devoted to the discussion of the measurement of "intelligence," which is a somewhat controversial issue, but a very interesting and relevant one. On the other hand, perhaps a little too much prominence is given to Professor Bowley's estimates of future populations, since these are based upon demonstrably false assumptions—namely, that the death rates will continue to be the same as in 1910-12, that the annual number of births will remain as in 1921-23, and that there will be no migration. Professor Greenwood's conjectures (published in *Metricron*, 7, 1925), which assumed an improvement of the death rates continuing to 1927, and that the births would decrease logarithmically, have a somewhat more plausible

basis; but, so far as births are concerned, this foundation too is more favourable to the increase of population than the facts.

These, however, are not points of much practical importance, and we can unreservedly commend the book, which should be very useful to all interested in the present position and prospects of our country.

### THREE BOOKS ON PATHOLOGY.

PATHOLOGY, instead of occupying, as heretofore, a merely subordinate position as the handmaid of practical medicine, has now established its claim to be considered an independent science. The new point of view has necessarily had its influence on methods of teaching and the character of textbooks, as is clearly shown in Professor OERTEL's book *Outlines of Pathology*.<sup>2</sup> The book is based on the method of teaching adopted at present in the McGill University, where pathology is dealt with primarily not as a preliminary medical subject, but as a scientific and cultural branch of knowledge. Completeness in detail, such as was aimed at in the older textbooks, is not its main purpose, nor are practical applications to the art of healing discussed to any considerable extent. The student is brought to the threshold of the subject, and an effort is made to unfold critically the origin of, and trace the different methods of attack upon, the great problems in pathology, and to emphasize its constant interactions with other sciences. The author considers that the increasing wealth of positive information which is at present scholastically handed to the student as a necessary equipment is bewildering rather than illuminating, and his endeavour has been to stimulate the student's interest and critical faculty rather than burden him with innumerable details, which he will discard, in the main, after his examination. The subject is developed in two main sections—on etiology, and on pathogenesis or the development of disease. Under etiology are considered, first, subjective or internal factors—namely, hereditary or ancestral qualities and individual or developmental qualities; and secondly, objective or environmental factors—namely, physical and chemical agents and organized parasites. Under pathogenesis are considered in the first place infection and immunity, or the interrelations between subjective and objective causes of disease; and secondly, pathological anatomy and histology, including the manner of development of morbid lesions. It may be said that these headings exhibit nothing new; the book does, however, exhibit a novel and striking difference from the older type of textbook in its more philosophical spirit, and in its recognition that pathology is something more than the mere description of anatomical lesions with passing references to their causes; that the foundations of the subject are to be looked for in such matters as the laws of heredity and somatic development, the reaction of cells to environmental changes, the nature of immunity, and the physical and biochemical relations of the cells. The author brings these and kindred subjects into prominence, and links them up with the facts of pathological anatomy. It is only by such a method that the student can be taught what pathology is.

Textbooks on pathology generally reflect to some extent the temperaments of their authors—anatomical, physiological, practical, or philosophical—but there appears to be a growing tendency to present the subject in its entirety and in all its aspects. Dr. POWELL WHITE's book on *The Principles of Pathology*<sup>3</sup> is an example of this tendency, or rather it is an attempt to lay the foundations of an all-embracing exposition of the subject which, in its entirety, would seem to be beyond the powers of a single author. It is, therefore, not a textbook on pathology, but a carefully drawn ground plan, starting from which the student may feel confident that he can build up the entire edifice without any fear of omitting important sections.

<sup>2</sup> *Outlines of Pathology*. By Horst Oertel. Montreal: Renouf Publishing Co. 1927. (Sup. roy. 8vo, pp. xi + 478 + vii; 131 figures. 10 dollars net.)

<sup>3</sup> *The Principles of Pathology*. By Charles Powell White, M.D., F.R.C.S. Publications of the University of Manchester, Medical Series, No. XVII. Manchester: The University Press; London: Longmans, Green and Co., Ltd. 1927. (Demy 8vo, pp. x + 278; 8 figures. 15s. net.)

<sup>1</sup> *A Survey of the Social Structure of England and Wales as Illustrated by Statistics*. By A. M. Carr-Saunders and D. Caradog Jones. London: Milford, Oxford University Press. 1927. (Demy 8vo, pp. xi + 249; 81 tables. 10s. net.)

Such seems to have been the intention of the author, and he has carried out his scheme with considerable success. The basis of an attempt of this kind must necessarily consist in a satisfactory scheme of classification—one that will enable every detail to be included and to be put in its proper place in relation to other details—and the author has placed classification in the forefront of his work. He lays down four main divisions of the subject—namely, morphological, chemical, physical, and physiological pathology, and deals with each of these along two lines—biostatics or morbid states, and biodynamics or morbid processes. The biologic and scientific aspect of the subject, which is too often neglected in ordinary textbooks, is therefore placed in proper relief. Considerable ingenuity is exhibited in the subordinate classifications adopted, among which may be mentioned the classification of pathological processes into (1) consecutive, or those which are the direct effect of injury in the widest sense of the term; (2) adaptive, or those which arise as a reaction against changes in the environment and tend to neutralize or compensate for injurious action; and (3) autonomous, or progressive processes which are harmful and neither adaptive nor reactive against changes in the environment. The value of a sound classification and nomenclature cannot be overestimated, and Dr. White's book is a contribution to this subject; but the work contains, besides, very good and concise descriptions of the morbid states and processes themselves, and such chapters as those on surface phenomena, surface tension, electric charge, adsorption, and diffusion are particularly clear and valuable. The book should assist the student in obtaining an insight into the scope of pathology, regarded as an independent science.

KARNSER's textbook of *Human Pathology*<sup>4</sup> presents the subject in the traditional form adopted in works on pathological anatomy—that is to say, it treats in the first instance of general pathological processes such as degeneration, inflammation, and tumour formation, and in the second part deals with the special pathology of the different organs. This arrangement is considered by the author to be in harmony with the position of pathology in the medical curriculum, and the best way of presenting the subject as an introduction to, and a basis for, the clinical branches of medicine. The more intricate problems of pathology are discussed in sufficient detail to permit of a definite understanding of the points at issue, and an attempt is made to distinguish clearly between fact and theory. The subject matter appears to be complete, and the book presents the broad facts of pathology in a manner suitable for the medical and biological student as well as for the practitioner of medicine desiring to keep abreast of this ever-enlarging subject.

#### DERMATOLOGY.

Dr. R. W. MACKENNA's textbook on *Diseases of the Skin*<sup>5</sup> has now attained the distinction of a second edition, although in doing so it has not undergone the usual increase in bulk, and the general characteristics of the original volume have been preserved. In reviewing this book on its first appearance we remarked that Dr. MacKenna had not succumbed to the lure of the coloured-plate. This time he has; in fact there are no fewer than thirty-six coloured illustrations in this edition, mostly, we should think, from photographs, although this is not expressly stated. Although too much store is often set upon coloured illustrations, which are not by any means always satisfactory, there is no doubt that in this instance they are very successful and form a most notable improvement on the former edition.

The advances in etiological research since 1923 are reflected in the present edition by additions to the chapter on diseases due to filter-passing viruses. Among these, owing chiefly to the studies of Pernau, herpes is now

included, whereas in the first edition it was included among the neurodermatoses. Dr. MacKenna also touches in passing on the interesting question of the relationship between the dermatotropic strain of the virus and the neurotropic strain, which, according to the researches of Lovaditi, is the cause of encephalitis letargica. He mentions also the recent attempts to treat lupus erythematosus with intravenous injections of certain gold preparations, such as krysolgan. He is not, however, enthusiastic about this line of treatment, and he is equally cautious on the subject of thallium acetate as a remedy for ringworm of the scalp. Here we note that he makes no reference to the convenient method provided of making a naked eye diagnosis of ringworm of the scalp with the help of the fluorescence of the infected hairs produced by ultra-violet light shining through the deep purple of Wood's glass.

Speaking generally, our examination of the second edition of Dr. MacKenna's book only serves to confirm the verdict given upon the first: that he has produced a textbook well above the average, thorough, practical, sound, and easy to read, which may safely be commended both to students and practitioners. The only fault we have to find is with the binding, which is not sufficiently strong; those who study the book as thoroughly and as often as it deserves will be fortunate if, in course of time, it does not come to pieces in their hands.

#### SURGERY AT THE SALPÊTRIÈRE.

THE second series of *Travaux de la Clinique chirurgicale et du Centre anticancéreux de la Salpêtrière*,<sup>6</sup> brought out by Professor A. GOSSET, fully maintains the high standard of matter and presentation set up by the first series, which was reviewed in these columns a year ago (1927, i, 144). Of the ten articles, Professor Gosset is personally responsible for four, solely in the case of two, and conjointly in the other two. The volume, which is generously illustrated, begins with a full account of the organization and activities of the department under his direction by Professor Gosset, who, in giving a brief historical sketch, pays a special tribute to his teacher and predecessor F. Terrier (1837-1908), who did so much to introduce surgical asepsis. Among the laboratories attached is a biological one under the care of Dr. J. Magrou, who has devoted much time to the investigation of vegetable cancer, and contributes an article on the tumours due to the *Bacterium tumefaciens*. Professor Gosset and M. J. Charrier describe the removal in two stages of tumours of the ascending colon—a method which they think likely to diminish the mortality from this operation. Dr. Robert Monod's report on the combined radium and surgical treatment of 75 cases of cancer of the cervix uteri is very encouraging, as many of the cases were sent in as inoperable, and 55 per cent. of the cases were well three years later. In a beautifully illustrated and detailed account of 38 cases of the strawberry gall-bladder Professor Gosset, with his collaborators MM. Ivan Bertrand and Georges Loewy, points out that in 20 of their cases the gall-bladder contained free mulberry calculi, and reiterates their opinion, expressed in 1920, that detachment of the lipid-laden villi is one, if not the sole, mode of the formation of cholesterol calculi. The strawberry gall-bladder, in their view, though not the result of inflammation, is pathological, and good results are obtained by cholecystectomy. Clinically the symptoms of a strawberry gall-bladder without calculi are the same as those of cholelithiasis. In an article on the surgical treatment of mammary cancer, based on Halsted's methods and dealing with 102 cases operated on between January, 1919, and January, 1927, Professor Gosset states that of the 84 traced, 47 are alive and well, 25 of them three years after operation. The indications, technique, and results of degastro-enterostomization are described by M. Marcel Thalheimer. The clinical and sigmoidoscopic aspects of chronic haemorrhagic and purulent proctitis are set out by M. Roger Savignac, who promises a further account of the etiology and treatment of this peculiarly obstinate affection. M. Raymond Bernard describes the technique of removal of malignant glands from the neck, and

<sup>4</sup> *Human Pathology: A Textbook*. By Howard T. Karnser, M.D. With an introduction by Simon Flexner, M.D. London: J. B. Lippincott Co. 1927. (Med. 8vo, pp. x + 890; 433 figures, 20 plates. 45s. net.)

<sup>5</sup> *Diseases of the Skin*. By Robert W. MacKenna, M.D., B.Ch.Ed. Second edition, revised and enlarged. London: Baillière, Tindall and Cox. 1927. (Roy. 8vo, pp. xii + 450; 146 figures, 36 plates. 25s. net.)

<sup>6</sup> *Travaux de la Clinique chirurgicale et du Centre anticancéreux de la Salpêtrière*. Publiés par A. Gosset. 2e. série. Paris: Masson et Cie. 1927. (Imp. 8vo, pp. 273; 134 figures. 65 fr. sans majoration.)

M. Maurice Boureau provides the results of twenty-seven years' experience as an anaesthetist; he has produced general anaesthesia 24,000 times, and has had only three deaths. He finds that pulmonary complications are much commoner in hospitals than in nursing homes, and ascribes this to the difference in the preparation of the patient, especially the hygiene of mouth and teeth, and to exposure in transit through cold passages. Professor Gosset, however, has the teeth specially examined and a solution of methylene blue applied to them.

### GYNAECOLOGY.

The second edition of Dr. JAMES YOUNG's *Text-book of Gynecology*<sup>7</sup> has recently been published, and the author is to be congratulated anew on a very satisfactory production. The plan of the book has not been altered, but fresh matter has been introduced in several chapters. Recent work on the physiology and anatomy of the corpus luteum has been included, and the discussion on the relation between the ovary and menstruation is well treated. In the treatment of carcinoma of the cervix the claims of radium are advanced. Heyman's figures of 40.5 per cent. of five-year cures are quoted in support of the author's leaning towards radium treatment as opposed to the Wertheim operation. Dr. Young describes Rubin's test for the patency of the Fallopian tubes, and a diagram of a simple apparatus for practical use is included. The chapter on ovarian tumours now contains an account of endometrioma of the ovary in accordance with the view set forth by Sampson of America. Apart from these changes, the book varies little from the previous edition. It is perhaps rather strango to see a British textbook of gynaecology with its title spelt in the American fashion, but this is a trifling matter in a work admirably suited to the needs of the final-year student and the recent graduate. The book has been greatly improved by being printed on more pleasing paper, and its continued success may be looked for.

### NOTES ON BOOKS.

THE author of *The Essentials of Otolology*<sup>8</sup> states that "there are very few books on otology that the student can read intelligently." The meaning of this sentence, which appears to lay the onus of intellectual quality on student rather than book, is not perfectly clear, but if it is intended to imply that there are very few books on otology intelligible to the average student a singular want of appreciation of contemporary otological literature is displayed. Such works are quite numerous, and the claim inferred by this remark is the more unfortunate because, after careful perusal, the book by Dr. McAULIFFE cannot be given a place among them. The more it is studied the greater appears the chaos which the author has contrived to compress into a comparatively small space. The chapter on tests, for example, which is placed just in the middle of the book, contains some sixteen pages, of which no fewer than thirteen are devoted to an analysis of nystagmus. Anatomical studies, which are nowhere more important than in dealing with diseases of the ear, are relegated to the end, the place usually assigned to deaf-mutes, who are certainly not of much importance to students. "When to tie off the jugular" provokes a paragraph of five lines, which do not tell the reader, looking for guidance on difficult points, "when." The radical mastoid operation is dismissed in a few lines, and its results are condemned as altogether unsatisfactory. We should perhaps add that the book is well bound and printed on good paper, and that it contains a few good illustrations of the simple mastoid operation, after Dr. Whiting's well-known work on the modern mastoid operation, without the usual acknowledgement.

Mr. CHARLES WICKSTEED ARMSTRONG is a eugenicist, who is convinced that the English, and probably other races, are degenerating as the result of democracy and humanitarian legislation. In *The Survival of the Unfittest*<sup>9</sup> he states his conclusions that "a differential birth rate, obliging all ranks

to recruit from the classes below, must cause the rot to spread slowly upwards"; and that since the war the process has been hastened "by legislation more and more dysgenic, better and better calculated to hasten the catastrophe which we refuse to see approaching." By improving environment appearances can be improved for a certain time; but if the hereditary factor is neglected the time comes when improvement in environment can no longer prevent the downfall. The statesman, it appears, has not merely allowed breeding in man to go on haphazard; he has deliberately interfered with a view to helping the unfit to survive and reproduce, and "the extraordinary excuse for such interference with the divine plan of evolution has been that in man natural selection is no longer operative." The worst instance of man's interference is, in Mr. Armstrong's opinion, the National Insurance Acts. The only national insurance which he finds not prejudicial is that against old age, and to some extent that against widowhood. As Mr. Armstrong thinks that "every sane man knows instinctively that the proper cure for unemployment is useful relief work" he would seem to be afraid of the conclusions which really follow from his arguments. Mr. Armstrong's solution for our troubles is to establish a settlement of eugenicists. He suggests the South-Eastern Pyrenees as the home for the settlement, where the cult of beauty and good government could be developed. It is perhaps disappointing that a tirade against the doubtful blessings of democracy and humanitarian legislation should end in Utopia, but, as Mr. Armstrong says hopefully, the world owes its progress to the unconventional, and the "crank" of to-day may be the revered teacher of to-morrow.

Mr. A. L. ROWSE, Fellow of All Souls, has contributed to the General Series of the *Psyche Miniatures*, which must be distinguished from the Medical Series, a charming essay *On History: A Study of Present Tendencies*,<sup>10</sup> dedicated to the members of the Essay Club at Christ Church, where presumably it was read. It is arranged in chapters, with the headings "An analogy," "The present situation and the problem," "A sketch of a theory of history and applications," and a Conclusion. From the time of Hallam and Macaulay, and throughout the Victorian age, the attitude of historians can be summed up as the glorification of the English Constitution; but this tradition has faded away, and historians have now fallen back more and more upon the solid work of arranging and editing sources, and upon a more exacting standard of critical methods. But with its advantages this method has its drawbacks, and the present generation might be criticized for burdening their books with notes and addenda which, from lack of constructive power, such as Macaulay so pre-eminently possessed, have not been incorporated into the body of the text. His remark that "a whole essay might be written alone on the tyranny of references" may apply even to some medical writers. He concludes on the cheerful note of Lord Acton's dictum, the study of history "fulfils its purpose even if it only makes us wiser, without producing books, and gives us the gift of historical thinking, which is better than historical learning."

In commemoration of the seventieth birthday of Professor Bernhard Nocht, director of the Institute of Tropical Diseases in Hamburg, a collection of articles on tropical diseases<sup>11</sup> has been published by his friends and pupils. Over ninety special contributions have been sent in from investigators in twenty-eight different countries, and the book is a handsome tribute to a world-renowned scientist. Numerous illustrations and tables are incorporated in it, and there is a good photograph of Professor Nocht.

The fifth volume of scientific reports<sup>12</sup> from the Institute for Infectious Diseases at Tokyo, edited by Dr. YONENJI MIYAGAWA, contains thirty-six papers (of which twenty-eight are in English and eight in German) devoted to bacteriology and serology, pathology, biology, chemistry, parasitology, and medical entomology. The subjects discussed include the pathogenesis of experimental pneumonia in rabbits, antirabic vaccination, standardization of cow-pox lymph, the oxidase reaction in bacteria, chicken sarcoma, the function of the supranal cortex, potassium deficiency in animals and birds, and experimental studies in hook-worm infection.

## EPILEPSY.

THE subject of epilepsy—or “the epilepsies,” to use a convenient and more elastic terminology—has of recent years been attracting the attention of neurologists, psychologists, and biochemists, who have severally approached its many problems from somewhat different angles of study. The older conceptions of epilepsy tended to regard it as a disease of the brain itself—some peculiar inborn abnormality of the nerve cells by reason of which recurrent explosions, so to say, of neural energy occurred, with the production of convulsions or other manifestations of the disease. The failure of many careful and prolonged histological studies to find any adequate structural changes to account for the symptoms led gradually to the abandonment of the conception that epilepsy is in any sense essentially or primarily a disease of the brain itself. And more modern trends in the study of disorder of function in the nervous system, as opposed to that of actual structural changes, have gone far to widen our conceptions of the epilepsies, both in regard to their forms and their etiology. That rigid barrier—so artificial but yet so attractive on paper—between epilepsy and hysteria has been seriously breached by many clinical observations, and this in itself is an advance of no small value; recent investigations of the epilepsies, moreover, may fairly be held to illustrate the advantages of breaking down the hard-and-fast line of demarcation between “organic” and “functional” disease.

Dr. Kinnier Wilson has lately published a valuable paper on “Epileptic variants”<sup>1</sup> which brings into prominence that wider conception of the epilepsies which now prevails, both as regards their forms and their causes. In this article in the *Journal of Neurology and Psychopathology* attention is drawn to the view that the clinical phenomena of the epilepsies must be considered as escapes from physiological inhibitions, and that such escapes of function may be exteriorized in the form of motor, sensory, or visceral symptoms. Thus on the motor side Dr. Wilson recognizes five variants: (1) myoclonic or regional epilepsy, (2) epilepsy partialis continua, (3) tonic epilepsy, (4) co-ordinated epilepsy, (5) inhibitory or akinetic epilepsy. The sensory variants he classifies as follows: (1) reflex epilepsy, (2) sensory epilepsy, (3) affective epilepsy. Among the visceral variants he places that peculiar symptom-complex termed by Gowers vaso-vagal attacks, which that distinguished author fully described twenty years ago in his book *The Borderland of Epilepsy*. It is interesting to note that under the term “inhibitory or akinetic epilepsy” Dr. Wilson places that peculiar disorder of function cataplexy, a condition which has lately been attracting much attention, especially since the publication of the valuable paper by Dr. W. J. Adie on narcolepsy,<sup>2</sup> with which the cataplectic attacks seem to be so closely associated.

Dr. James Collier's Lumleian Lectures (of which

we published abstracts in our last issue at page 557) cover wider ground, embracing as they do the whole subject of epilepsy. On the etiological side Dr. Collier brings forward convincing arguments in favour of the view that epilepsy is essentially due to a metabolic disturbance, although the exact nature of these disturbances is not particularized; indeed, we gather that in his view the disturbance need by no means always be of exactly the same order. While many may be found to accept freely such a hypothesis as an acceptable explanation of that condition which is termed idiopathic epilepsy, we feel that the lecturer is on less sure ground in maintaining the same thesis for cases of organic epilepsy—that is, those cases associated with some gross organic lesion of the brain, such as a tumour. Even in this latter variety, however, a good deal of evidence is available in support of his view, especially the experience of the enormous numbers of wounds of the skull and brain in the war with the relatively very small incidence of consecutive epilepsy, as well as recent experimental work of great interest which is quoted in the lectures. Interesting parallels are drawn by Dr. Collier between the clinical phenomena of migraine, pyknopsy, narcolepsy, vaso-vagal attacks, and even tetany, the opinion being submitted that migraine, for example, may be regarded as a particular form of local epilepsy, associated with a local swelling of the brain, analogous to angioneurotic oedema and dependent again on some metabolic dyscrasia.

Dr. Collier and Dr. Wilson agree in their inability to separate narcolepsy from epilepsy, differing in this respect from Dr. Adie, who has attempted to distinguish clearly between them. A loss of function is regarded by Dr. Collier as the essential feature of epilepsy, agreeing with the physiological inhibition defined by Dr. Wilson. If this view be correct the positive symptoms of any epileptic attack must be regarded as release phenomena, occurring at lower levels of the nervous system. Such a physiological conception is certainly attractive, and appears to fall into line with the recent monumental researches on conditioned reflexes of Pavlov and his colleagues, who have shown that sleep itself is but a matter of internal inhibition—a discovery which seems to dispose of the idea that release symptoms must of necessity be “positive,” using that term in the sense defined by Hughlings Jackson. The Lumleian Lecturer is undoubtedly in advance of current opinion in his contention that the ordinary fainting or syncopal attack is not to be clearly separated from the epilepsies either on etiological or on physiological grounds. It may be admitted at once that cases are to be found in which the two seem to merge almost imperceptibly into one another, yet general experience is still, we think, far from admitting their identity.

Much has been written of recent years on the psychological aspects of epilepsy; some, indeed, have gone so far as to claim for it an inevitable mental causation as well as a particular mental “make-up.” It is probably true to say that the balance of opinion is not in favour of accepting such a view, but this is far from denying the powerful part played by the emotions in the production of attacks. Such a concession, however, to the psychologists does not imply a surrender of the metabolic theory. The correlation between body and mind is constantly being displayed in all the functional disturbances, whether these be exteriorized in symptoms referable to the nervous system or to others, such as the respiratory or the digestive. The elucidation of problems such as these is a task which modern medical

<sup>1</sup> *Journal of Neurology and Psychopathology*, viii, No. 31, 223.

<sup>2</sup> *Brain*, 1926, xlix, 257.

research is happily well disposed to undertake, and in such a field the further study of the epilepsies may furnish fruitful results. Biochemical studies of epilepsy have been numerous, but they cannot as yet be said to have achieved results which carry much conviction in regard to the essential etiology of its many variants. Nor, we fear, can a claim be made out for any great advance in treatment. On the metabolic side the multitude of "cures," such as vegetarian diets, fat-free diets, ketogenic diets, and others, is in itself a confession of failure. A close study of the metabolism in the condition known as status epilepticus—where, as Dr. Collier rightly points out, a definite toxæmia must certainly be present—might succeed in throwing more light on this difficult problem, though the opportunities for such research are few and uncertain.

A healthy discontent with the mere label of epilepsy is the proper attitude of mind; the epilepsies should be regarded as symptoms, whose essential causes have as yet to be unravelled, possibly indeed varying with each individual case, whose peculiarities, therefore, are all the more deserving of careful study.

### BREAST-FEEDING.

A SURVEY of medical literature during the last decade or so clearly indicates the increasing importance attached to breast-feeding. As Dr. Frank Howard Richardson pointed out not long ago when discussing the progress of breast-feeding in New York State, "Even though much of this enlarging volume of medical attention has been concerned with public health measures rather than with private practice, still there has been a steadily increasing tendency on the part of students of infant health and nutrition to concern themselves with some of the multifarious problems connected with the natural feeding of children, as compared with an earlier (and still altogether too prevalent) tendency to experiment with artificial methods of nourishing babies." Nevertheless, it is still a difficult matter to obtain exact information, even from the most recent literature, on the prevalence and duration of breast-feeding in the community as a whole. It may, however, be taken for granted that breast-feeding is more usual in hospital than in private practice.

The findings of an investigation on "The prevalence and duration of breast-feeding in hospital practice" in the Obstetrical Unit of the Royal Free Hospital have been recorded and discussed by Professor Louise McLroy.<sup>2</sup> She remarks that in obstetrical departments it is the endeavour of the medical and nursing staffs to induce the mother to nurse her infant unless the mother is suffering from pulmonary tuberculosis or advanced cardiac disease, when lactation is contra-indicated. Owing to distance and other causes all the infants born in a hospital cannot attend its welfare clinic, many of them being taken to the local practitioner or to nearby welfare centres. This practice makes it difficult to obtain information as to the duration of breast-feeding. In the Obstetrical Unit of the Royal Free Hospital every mother is made to nurse her baby when possible, and every means available is taken to enable her to supply a sufficient quantity of milk for the needs of her infant.

Complications with the breast or nipples which

prevent suckling, as well as a deficient supply of milk, call for appropriate treatment. Professor McLroy stresses the importance of carious teeth and pyorrhoea as causes of failure in lactation, much improvement in the infant's weight chart often following suitable treatment of the mother's teeth. Further, during the last few months treatment of the nursing mother by artificial sunlight has been carried out, and the results, which will be published later, are said to be most encouraging. When the supply of milk is inadequate, and cannot be improved, supplementary feeds are given, in some cases twice daily and in others by alternate feeds. Fresh cow's milk is preferred to dried or condensed milk. Only where it is learned that home circumstances would not render cow's milk available is a dried milk given, so that the mother may be taught in hospital how to prepare it, and also that the infant may continue at home with the same method of feeding as it has had in hospital. Professor McLroy is positive that it is a mistake to carry out in hospital a method of feeding infants which is only possible for a trained staff, and which is beyond the capacity of the mother and her home surroundings. She points out that the infant suffers enough from its dislocation at the end of ten days without adding to its discomfort by complete change of food. It is, also, better to begin artificial feeding in hospital and to treat the breasts for the prevention of lactation in those cases in which, owing to occupation or the necessity of separation from the infant, the mother cannot nurse it. On an average 5.1 per cent. of the infants in the Obstetrical Unit of the Royal Free Hospital leave the hospital entirely artificially fed. A much larger proportion of artificially fed babies attend the welfare clinics, from which it may be gathered that all the mothers do not continue the methods they used in hospital.

In reply to a questionnaire in the form of a personal letter, the condition of 730 infants with reference to the method of feeding was investigated about nine to twelve months after birth. Of these, 333, or 45.8 per cent., were entirely breast-fed—among these there were 16 deaths; 33, or 4.5 per cent., had supplementary feeds after leaving hospital—among these there were no deaths; 7, or 0.96 per cent., had supplementary feeds while in hospital—among these there was one death; 320, or 43.7 per cent., had artificial feeding substituted after leaving hospital, and among these there were no deaths; while 37, or 5.1 per cent., were never breast-fed, and among these there were 3 deaths. Professor McLroy believes it desirable that all maternity hospitals should have a follow-up system in co-operation with the infant welfare clinics, so that supervision of the health of the nursing mother may be systematically carried out. It is open to question whether a delicate mother should entirely feed her infant; supplementary feeds may be necessary to keep it in health, and were found to be more satisfactory than entire artificial feeding.

In this investigation the infants in satisfactory home surroundings were found to be in better health than those living under poorer conditions, even when entirely breast-fed. Although among the poor breast-feeding is more economical than any method of artificial feeding, yet its benefits are apt to be counteracted by the struggle for a bare existence and unsuitable home conditions. It may therefore be concluded that, although nine months' breast-feeding is the ideal to strive for, yet care and attention must be given to the nursing mother if this is to yield better results than supplemented artificial feeding.

## HARVEY TERCENTENARY CELEBRATION.

WE are asked to make it known that the Royal College of Physicians of London has set aside a proportion of tickets for such Members and Licentiates of the College as may wish to be present at certain parts of the Harvey tercentenary celebrations. One hundred tickets are available for the conversazione at the Hall of the Merchant Taylors Company at 9 p.m. on the evening of Tuesday, May 15th; each ticket-holder is invited to bring a lady with him. A similar reservation for Members and Licentiates, without ladies, has been made for the banquet at the Guildhall at 7 p.m. on the evening of Wednesday, May 16th. There will be an inclusive charge of two guineas for each dinner ticket, which should be sent as soon as the applicant receives notice that a ticket has been allotted. Some tickets will also be allotted to Members and Licentiates for the demonstrations in the Physiological Department of University College, Gower Street, on Tuesday and Wednesday mornings, May 15th and 16th, from 10.30 to 12.30 o'clock, at which, along with demonstrations of recent additions to our knowledge of the circulation, will be shown a film, specially prepared for the occasion by the Royal College of Physicians, displaying a reproduction of Harvey's original experiments. Members and Licentiates are advised to make early application, as tickets will be allotted to both London and provincial applicants as far as practicable in the order of application. Letters should be addressed to the Registrar, Royal College of Physicians, Pall Mall East, S.W.1.

## FIRST-AID SERVICE ON THE ROADS.

THE development of a first-aid service to meet the great increase in road accidents forms the main subject of the ninth report of the Home Service Ambulance Committee of the Order of St. John and the British Red Cross Society, covering the period from April to the end of December last year. We have referred here from time to time to the progress made in this direction by the committee, but the most recent report contains a more comprehensive review of the methods adopted. All over the country last year, the report states, members of the organizations concerned spent their week-ends and holidays on the roads equipped to render assistance to the injured. First-aid boxes are being set up on many main roads. Individual members living in villages on or near main roads have notified the police and other officials of their readiness to give their services when required. The committee hopes to be able ultimately to provide permanent first-aid posts with the necessary equipment and trained personnel, in addition to maintaining patrol services and establishing temporary stations when the need arises. This system will, it is believed, do something to relieve the pressure on the voluntary hospitals created by the demand for treatment of minor injuries, and will ensure that more serious cases are not subjected to the unskilful and often harmful handling of persons who have no qualification but good intentions. It is suggested that the wide diffusion of road accidents masks the extent of their effects in death and injury. In connexion with the ambulance service proper an increase in the demand for transport for the sick and injured is again noted. The average number of cases carried per ambulance last year was 267.7 against 243.2 in 1926 and 125.6 in 1920. These figures reflect the increasing use being made of the ambulances by members of the medical profession to secure for their patients the advantages of modern systems of diagnosis and treatment dependent on mechanical apparatus. With adequate transport available it has been possible to bring the whole country within reach of the facilities available only in hospitals and allied institutions. Most of the ambulances, it is interesting to note, are now in the care of detachments of the Red Cross

Society or divisions of the St. John Ambulance Brigade, and it is claimed that this voluntary service is definitely superior to that under the control of public authorities. Like the voluntary hospitals, the ambulance units, although depending on local support, have to bear a heavy burden in dealing with strangers who become involved in road accidents in their districts. We may recall that our late Editor, Sir Dawson Williams, was a member of the Home Service Ambulance Committee until his death, and took a warm personal interest in its valuable work.

## CARDIAC TONICS.

THOUGH much has been written on the subject of heart tonics, the uncomplicated effect of these drugs upon the heart has never been clearly defined. Most of the older investigations were made on the frog's heart under conditions which do not exist in normal life, and the conclusions drawn from these experiments are unconvincing. Study of the isolated heart, and even of the heart left in the body of the frog, are not suitable for drawing deductions as to the effect of heart tonics in man. Since the chambers are more or less empty in the isolated heart, the organ performs much less work than in the living animal. Moreover, experiments on the whole frog, though furnishing many very important facts, do not indicate simply the direct effect of drugs on the heart, since this effect might be complicated by the drug action on the nervous system, which might in turn modify the heart rate, with a resulting alteration in output. Again, cardiac tonics might conceivably affect the vessels, and, consequently, the venous inflow and the ventricular output, thus obscuring the direct cardiac effect of the drug. In the *Journal of Physiology* for February 10th, 1928, there is an interesting paper by Mr. R. Bodo, who describes a series of experiments in the department of physiology and biochemistry of University College Hospital. Mr. Bodo tried to obviate the defects in previous work; dogs were used, and Starling's heart-lung preparation seemed to be the most suitable, since in it the environmental conditions of the heart—namely, the temperature, the composition, alkalinity, volume, and pressure of the entering blood, and the opposition to the outflow offered by the arterial resistance—can be exactly controlled, changed within very wide limits, or kept unaltered during the whole of the experiment. A clear definition of heart-tone is essential, and Bodo adopts Starling's conception of the mechanical efficiency of the muscle fibre—that is, the relation of the mechanical energy to the total energy liberated. Among the heart tonics investigated were digitalis, caffeine, camphor, and strychnine, both as regards their effect on the heart muscle fibres and on the coronary circulation. In order to obtain further evidence as to a possible relation between these two effects, certain other drugs, not usually considered as heart tonics, but known or suspected of having an effect on the coronary circulation, were examined. These were the nitrites (both amyl and sodium), insulin, pituitrin, and quinidine. The mechanism of tonic action was found to be the direct opposite of that which occurs during dilatation of the heart. When the tonic effect begins to be apparent there is a transitory increase in the output and a gradual decrease in the heart volume, until a state is reached at which the output is again equal to the inflow, but the heart volume is smaller. Decrease in volume is said to be the important therapeutic effect of tonics upon the heart. Judged by these experiments digitalis, caffeine, and insulin produce their tonic effect by enabling the heart to expel the same amount of blood with a smaller average heart volume. This effect is, after digitalis administration, delayed but lasting; after caffeine it is relatively rapid in onset, but evanescent; and after insulin it could be observed only once in each preparation. The

common view that digitalis increases the diastolic volume is said to be certainly incorrect. Camphor, sodium nitrite, pituitrin, and quinidine cause dilatation of the heart, but strychnine and amyl nitrite have no cardiac tonic effect. Digitalis, caffeine, camphor, and the nitrites increase the coronary flow, the two former only slightly, the two latter in a very high degree; while pituitrin, quinidine, and insulin diminish the coronary flow, the two latter only in large doses, small doses being without effect. Apart from the case of pituitrin, there exists no obvious relation between the tonic effect and that produced on the coronary flow by administration of these drugs.

#### MATERNAL MORTALITY IN CANADA.

At the last annual meeting of the Canadian Medical Association, held in Toronto, Dr. Helen MacMurchy read a valuable paper on maternal mortality in Canada, which has now been published in the journal of the association.<sup>1</sup> She showed that the maternal mortality for the year 1925-26 (the fifty-ninth year of the Confederation of Canada) was 1,532, a rate of approximately 6 per 1,000 living births. Examination of the previous medical history of these 1,532 mothers elicited the fact that in 727 the health had not been good, and 68 others were destitute. Nearly all these 795 deaths, Dr. MacMurchy considers, might have been prevented by proper pre-natal and domiciliary care, good nursing, and adequate medical attention. There were 226 deaths from cardiac disease; the number of mothers reported as having tuberculosis was 96, and 19 were stated to have been exhausted by too frequent pregnancies. Among the special causes of death sepsis came first, occurring in 418 cases, or 27 per cent. of the total maternal mortality. Haemorrhage caused 357 deaths, or 23 per cent.; toxæmias of pregnancy 344 deaths, or 22 per cent.; long and difficult labour 87 deaths, or 5 per cent. This gives a total of 788 deaths from haemorrhage, toxæmias, and dystocia, and nearly all these might have been prevented by proper ante-natal care. Pituitrin was used in 327 cases, and in three of these rupture of the uterus occurred. Finally, the histories show that of the 1,532 women who died, 1,302 had had no ante-natal care, and in 128 cases the medical practitioner was not called until labour had begun, while in 237 no doctor was in attendance at all. Surveying the position, Dr. MacMurchy finds little evidence of progress during the last twenty-five years. Much more, she thinks, could be done to inform prospective mothers and their husbands about the need for ante-natal care, and there are still some medical practitioners who do not seem to realize the importance of this prophylactic measure. She notes that of the 244,000 births in Canada during the year, 38,634, or 16 per cent., took place in hospital.

#### DISEASE OF THE PULMONARY ARTERY.

THERE is little opportunity of studying primary disease of the branches of the pulmonary artery in the lungs, but it is a disease which may sometimes be recognized clinically, and an interesting paper by Clarke, Coombs, Hadfield, and Todd on certain abnormalities of the pulmonary artery<sup>2</sup> affords a means of becoming acquainted with its main features. Five cases are described: one a clear case of syphilitic disease; the second an infant with patchy peribronchial fibrosis of the lungs and small cysts lined with bronchial epithelium; the third an infant in whom the sole changes were a dilatation of all the pulmonary branches without any histological alteration, and a defect in the interventricular septum; the fourth a girl of 5 years with marked "nodoso atheroma" of the pulmonary artery and its branches, with endothelial proliferation of the capillaries of the muscular coat and cellular infiltration at the junction

of intima and media; the fifth a woman of 22 years with primary arterio-sclerosis of both lungs. The last case is, perhaps, the most interesting. Apart from the disease in the lungs and its secondary effects—hypertrophy and dilatation of the right heart and pulmonary artery, dropsy, and visceral congestion—no other pathological condition was present. There was a nodular thickening of the intima of all the intrapulmonary arteries down to those with a diameter of 1 mm., the plaques being almost acellular and exhibiting in their central parts a few lipid clefts and scanty lipid phagocytes. In addition all the vessels, including the main pulmonary arteries, showed a diffuse increase in the elastic tissue. The fibrosis of the lung, especially at the hilum, appeared to be more marked than is usually the case in chronic venous congestion. There was nothing in the history to throw light on the etiology of the condition. The patient had suffered from breathlessness and nocturnal dyspnoea from the age of 6 years, the onset coinciding with an attack of scarlet fever. During the last few months of life she suffered from dropsy, orthopnoea, and cyanosis of sufficient intensity to suggest a congenital defect. Beyond a persistent increase in cardiac dullness to the right no definite signs were found in the heart, and the pulse was always recorded as being regular in force and frequency. The grounds on which the diagnosis of pulmonary arterio-sclerosis is based are stated by the authors to be deep cyanosis coming on at an age which precludes the diagnosis of congenital anomaly, without physical signs of pulmonary or cardiac disease severe enough to account for the cyanosis. The diagnosis is strongly supported if signs of right ventricular hypertrophy are discernible. Other clinical features are protruding eyes, an absence of clubbed fingers, and the pulmonary diastolic murmur which is sometimes observed. Dropsy develops late, but is apt to increase rapidly, and in some cases polyglobulism has been strongly marked.

#### THE GENERAL MEDICAL COUNCIL'S INCOME-TAX CASE.

WE referred in our issue of December 10th last to the appeals taken by the General Medical Council and its English Branch Council to the King's Bench Division of the High Court in an endeavour to establish the contention that the Councils' incomes derived from invested funds are not liable to income tax. Mr. Justice Rowlatt's decision was adverse to that contention, and his view has now been supported by the unanimous decision of the Court of Appeal. It is some small consolation to notice that the judges were agreed as to the value of the Council's work from the public point of view. The Master of the Rolls, for instance, in delivering the leading judgement in the Court of Appeal, said that one, at any rate, of the main objects of the Council was for the benefit of the public. Unfortunately such questions as this have to be decided in accordance with statute law judicially interpreted rather than in the light of pure equity. As the Master of the Rolls pointed out, "There is no general exemption of a charity from income tax . . . it must be shown that the income is the income of a body of persons established for charitable purposes only, and it is exempted only so far as it is applicable to such purposes." We do not propose here to follow the discussion as to the precise constitution of the Councils, the alternative constructions that can be placed on the preamble to the Medical Act, 1858, or the other legal niceties of the case, including the precise scope of the phrase "charitable purpose" as deduced from Statute 43 Elizabeth, ch. 4; such a discussion would be more appropriate to the columns of a legal journal than here. The root of the objection to the claim seems to lie in the requirement that the trust or other body shall be established for charitable purposes only; a mixture of

<sup>1</sup> Canadian Medical Association Journal, December, 1927.

<sup>2</sup> Quarterly Journal of Medicine, Vol. 21, No. 81.

public with professional duties seems to be fatal to any such claim to exemption from income tax. To quote the Master of the Rolls once more: "Unless the Council come exclusively and fully within the spirit and intention of the statute of Elizabeth I do not think they can claim exemption." It seems to us to be a serious blemish in the income-tax code that income which is in part expended in the discharge of very grave and responsible duties to the public should be liable to tax on the ground that the other part is not so expended. The exclusiveness of the charitable function does not seem logically to have any real bearing on the equitable claim to exemption for such income as is expended "charitably" in carrying out the duties of a statutory body such as the General Medical Council. Whether an appeal to the House of Lords will be made we do not know, but the Council's legal advisers will not be encouraged by the judicial views expressed.

#### BAYLISS AND STARLING MEMORIAL.

THE opinion has been widely expressed that there should be some memorial to record the great services rendered, both to the science of physiology and to its applications in the practical problems of medicine, by the labours of Sir William M. Bayliss and Professor Ernest H. Starling, who were intimately connected for so many fruitful years. The patient zeal of the one, the fire and enthusiasm of the other, and the eagerness of both to place their knowledge and experience at the disposal of other workers, have led to a universal appreciation of their services. The number of those in all countries who have profited directly from their help or indirectly by their influence is very great, and their writings stand as monuments to their industry and learning. A widely representative committee has been formed to issue an appeal for funds wherewith to commemorate the connexion with physiology of these great partners in a manner of which they themselves would have approved. The committee is of opinion that the most fitting memorial would be the creation at University College, London, of a Bayliss and Starling Studentship, open to any graduate in science of any university, or any graduate or undergraduate in medicine of suitable standing, to enable him to spend a year or more in such training in physiology and biochemistry as would fit him for research. Subscriptions may be sent to Professor C. Lovatt Evans, F.R.S., at the Institute of Physiology, University College, Gower Street, W.C.1. (Cheques and postal orders should be crossed, and endorsed "Bayliss-Starling Memorial Fund.") The Governing Body of University College has agreed to assist the appeal by remitting all fees payable by the selected candidate.

#### HEALTH IN INDUSTRY.

Is the field of preventive medicine the increasing attention now given to health in industry, to accident prevention, and to welfare work constitutes an interesting development in social organization, involving as it does the co-operation of the State, the employers' associations, the workers' trade unions, and numerous private individuals. The second annual report of the Industrial Health Education Society, for 1927, illustrates one side of the movement in which medical practitioners play an important part, in company with employers and labour organizations. In the course of the year the work of the society has extended considerably, and the increasing demand for its services shows a widespread interest among workers in occupational diseases and their prevention. The main purpose of the lectures given has been to convey information to those liable to be directly affected, but the discussions which have followed the addresses given by medical practitioners have served a very useful purpose by bringing to light complaints which had previously been known only to those engaged in the particular occupation concerned. Rheumatism appears to be the most common trouble in industry, and

a leaflet on the subject has been prepared for circulation by the society by Professor E. L. Collis. Another, on "Mule-spinner's cancer," by Dr. Prosser White, is in course of preparation for distribution among cotton operatives. The advancement of education in industrial health should be assisted also by the establishment of the Home Office Industrial Museum, which is a permanent exhibition of methods, arrangements, and appliances for promoting safety, health, and welfare among workers in manufacturing industries. It is the first of its kind in this country. The descriptive catalogue which has been prepared (obtainable from H.M. Stationery Office, Kingsway, W.C.2, price 3s. 6d. net) is designed to serve not only as a guide to the museum, but also in some measure as a handbook on the subject. Sections in the museum are given to accident prevention and safety devices, illustrated by examples and photographs, to labour-saving devices, and to welfare; but medical interest will centre mainly in the section devoted to industrial diseases, dealing especially with anthrax, lead poisoning, silicosis, and dermatitis. Photographs are employed to show preventive methods adopted in various industries; charts indicate the incidence of the diseases, models illustrate the lesions they produce, and micro-photographs of pulmonary conditions are exhibited. Doctors who practise among industrial workers liable to occupational disease should find the health section of the museum a useful source of information.

#### THE NEW IRISH FREE STATE MEDICAL REGISTER.

THE new Register under the Saorstát Éireann (Irish Free State (Medical Practitioners) Act, 1927, will, as announced in our advertising columns, be established on May 26th, after which date no person will be entitled to any of the rights and privileges of a registered medical practitioner unless his name appears therein. Such a person will not, for example, be entitled to recover fees for advice or attendance, or to hold any public medical appointments in the Irish Free State, even though his name appears in the general *Medical Register*. Any person whose address in the general *Medical Register* is outside the Free State must, to be entered in the new Irish Register, make application to the Medical Registration Council, Room 123, Custom House, Dublin, giving full name, address, and qualifications, between April 25th and May 26th. Persons whose addresses in the general *Medical Register* are in the Free State are entitled to be entered in the new Register without application, but it is suggested that all who desire to be registered should make application, particularly if they have changed their address since the beginning of the year. Those who are not entered on the new Free State Register at its establishment can only be registered subsequently on payment of the prescribed fee.

At the meeting of the Royal College of Physicians of London, held on April 2nd, Sir John Rose Bradford, K.C.M.G., M.D., F.R.S., was re-elected President.

THE KING has made the following appointments to His Majesty's medical household in Scotland: Honorary Physician, Ashley W. Mackintosh, M.D.; Honorary Surgeons, John Marnoch, C.V.O., and John Fraser, M.C.; Honorary Surgeon Oculist, Arthur Havens Sinclair, M.D.

At the last meeting of the Council of the Royal Society of Medicine the Nichols Prize was awarded to Dr. Peter L. McKinlay and Dr. Remington Hobbs, the prize being equally divided between them. This prize, of £250, under the will of the late Dr. R. T. Nichols, is offered every three years for the most valuable contribution by a British subject towards "The discovery of the causes and the prevention of death in childbirth from septicaemia."

## THE ECONOMICS OF MENSTRUATION.

It is noteworthy that during recent years the physiological nature of the menstrual cycle has received more general recognition, and there has been some tendency to deprecate the view of this period as a time of disability and ill health. While this attitude of cultivating healthy-minded indifference to menstruation should go far towards preventing many, if not most, cases of dysmenorrhoea, it is still urged that the industrial employment of women is always bound to be unsatisfactory on account of the economic loss entailed by an unreliable worker, and it is often alleged that women are greatly handicapped in professional and business life by physiological instability, said to be the natural consequence of a conspicuous monthly rhythm to which all their functions are subject. For some years past the Industrial Fatigue Research Board has been conducting investigations into the effect of the menstrual cycle on working capacity, and in a recent report<sup>1</sup> two lines of study are considered.

*Psychological Considerations.*

Miss S. C. M. Sowton and Dr. C. S. Myers deal in the first part of the report with the influence of the menstrual cycle on mental and muscular efficiency. The subjects of the investigation were arranged in two groups, of which the first, "A," consisted of thirteen university students, and the tests consisted of the "sparring" tests and a simple form of "number-checking," which were employed every week-day at the same time each morning during two successive terms. The subjects were unaware of the exact nature of the investigation; details of the occurrence of the menstrual period were obtained by a simple procedure, a short daily bulletin of the subject's general condition at the time of the test being recorded, and the occurrence of the period being noted among several other general observations, including such occurrences as headaches, excitement, and worry. The influence of practice soon made itself evident in these university students, and the vacation considerably interrupted the work, so group "B," consisting of sixteen industrial girls, was chosen. The test chosen was a modified form of "number-checking," with the introduction later of the "dotting" test, while the experiment was continued for six consecutive months. The results of both series of experiments were analysed by means of composite curves and other statistical methods, and before considering the conclusions to be drawn from the investigations the report enters very fully into the efficacy of the tests and the validity of the deductions. The results in each individual case are carefully scrutinized. Of the twenty-nine subjects seven had to be rejected owing to insufficient data being obtained or to gross irregularity of performance, and in one case because of illness. Of the remaining twenty-two, five showed no alteration in performance of the tests at the menstrual period; in four there was a better performance; in nine the performance was worse at these times or just before them; while four showed a better or worse performance according to their stage of familiarity with the tests. After discussing various points in regard to social status, the feeling of pleasure or displeasure at the tests, general physical fitness, and other matters, the report concludes this part of the work by saying: "Any lowering of efficiency at the tests which occurred at or near the menstrual period was not in general greater than that which occurred at other times—that is to say, no experimental evidence was obtainable that the menstrual period in normal women is associated with serious incapacity for mental or muscular work."

*Physiological Considerations.*

In the second section E. M. Bedale considers the relation of the menstrual cycle to general functional activity. A three months' study of a single subject under conditions controlled as closely as possible was made in a healthy woman, aged 30. Observations were made twice in twenty-four hours of the body temperature, the basal metabolism, pulse rate, blood pressure, and respiration rate in the post-absorptive resting condition, the vital capacity, and certain ergometer experiments. The diet was fixed, and

<sup>1</sup> Industrial Fatigue Research Board, Report No. 45. London: H.M. Stationery Office, 1928. Price 2s. 6d.

the hours of bed, exercise, and occupation were all scheduled. The subject knew the purpose of the experiment, but had no prejudices as to the result. The work was to a certain extent disturbed by the delayed onset of the period in the second month, and by a general deterioration of vigour which set in about the middle of the experiment. A simple statistical device, slightly modified from one used by Moore and Barker, was employed to analyse the results at the end of the experiment, and the conclusions reached may be summarized in the following quotations:

"The evidence of the present experiments seems to be that a periodic heightening of functional activity above the average occurs late in the intermenstrual phase of the monthly cycle, and that a corresponding reduction below the average is found shortly before or at the onset of menstruation."

"There seems no reason to think that the fundamental physiological rhythm in women is such as to affect, either considerably or constantly, the quantity or quality of their industrial work, provided always that no pathological conditions are present."

The general deductions from this report are of great economic importance, since the work tends to confirm the result of other recently published investigations on the menstrual cycle. It may now be asserted more definitely that this physiological phenomenon has, as a rule, no noticeable effect on working capacity among normal healthy women, and such a statement will be of special interest to those concerned in industrial matters.

## JOSEPHINE BUTLER.

## CENTENARY TRIBUTES.

It seems a long time since the activities and adventures of the early suffragettes. How much more remote are the days of Josephine Butler, a great part of whose life was devoted to working for the repeal of the Contagious Diseases Acts, 1864-69. In an endeavour to illuminate this shadowy period for the benefit of the present generation, and also to keep green the memory of a great and noble woman who was born one hundred years ago, Dame MILlicent Fawcett has compiled a book entitled *Josephine Butler: Her Work and Principles, and their Meaning for the Twentieth Century*.<sup>1</sup> To many people to-day her name is unknown, and after reading this book it must come to many as a surprise that in the years 1869 to 1886 it was a household word, either for warm praise or bitter denunciation, according to the views held on the work to which she had devoted herself. Sixty years ago it was unknown for women to speak in public; two years later, in 1870, Mrs. Butler was addressing mixed audiences all over England on the subject of prostitution. During those years, when prolonged and furious controversy raged round the question of the "State regulation of vice," Mrs. Butler was the central figure, not only in this country, but also on the Continent. It is difficult for us to realize the courage and intense conviction needed in those days for a woman to challenge public opinion on such a subject. Josephine Butler, drawn irresistibly to the work, inspired by her valour a band of men and women who gathered round her. "Mrs. Butler was the head and front of the movement throughout, her beauty, her grace, her eloquence, and indomitable courage won adherents on every side and secured the victory for us at last"—so wrote Dr. Bell Taylor.

About 1868 great alarm was felt at the increase of venereal disease, not only in the fighting services, but also in the civil population, and so the first of the Contagious Diseases Acts was introduced and readily passed. The system of regulation of prostitution then existing in France was regarded, almost without exception, by the medical profession and police administrators as the only method of dealing effectively with this problem. Under the French system women registered as "prostitutes" were set apart in certain houses "tolerated" or licensed by the

<sup>1</sup> *Josephine Butler: Her Work and Principles, and their Meaning for the Twentieth Century*. By Millicent G. Fawcett, G.B.E., and E. M. Turner. London: The Association for Moral and Social Hygiene. (Cr. 8vo, pp. vii + 164; 1 portrait. Paper cover, 1s. 6d.; cloth, 2s. 6d.)

police. The inmates of these houses could be medically examined at stated intervals, and were subject to the control of specially appointed police and medical officers. In France such control operated as a police measure, but in England it was inaugurated by Act of Parliament. The Contagious Diseases Prevention Act (Women) had been passed in 1864, and further Acts were thought necessary in 1866 and 1869. They applied at first to fourteen naval and military stations, but it was intended by degrees to extend their operation throughout the country. Mrs. Butler was firmly convinced that such State regulation of prostitution and the traffic in women and children were interdependent; that the licensed house constituted the chief market for the traffickers; and that the only effective way to abolish the traffic was to raise continuous and uncompromising opposition to official regulation of vice in every shape or form. She felt strongly that such regulation infringed the rights of women as citizens. In her speeches and writings she appealed again and again to the main principles of the British Constitution, above all to the famous words of the Great Charter—"To no man will we sell and to no man will we deny or delay right or justice."

The first association formed to oppose the Acts was inaugurated in 1869 at Bristol, following the meeting of the Social Science Congress, at which the Acts had been discussed. Almost simultaneously the Ladies' National Association for the same purpose was formed, and the two societies worked together in the closest harmony until success was at last achieved. The fight was long and arduous, and not (incredible as it may seem) without physical danger for Mrs. Butler, but victory was finally

hers in 1886, when the Contagious Diseases Acts were totally repealed. The direct but later consequences of this accomplishment are manifold. Dame Millicent Fawcett appends a list of these results, with the dates of their achievement. The year 1927 saw the publication of Parts I and II of the League of Nations Experts' Report on the Traffic in Women and Children,<sup>2</sup> which referred appreciatively to the great campaign of Josephine Butler. This report endorses for the world all the principles for which she fought in this country. What the report proclaims now, with the authority and prestige of the League of Nations behind it, one woman dared to say fifty-eight years ago under very different conditions. To her belongs the honour of being the first to organize a challenge to the State regulation of vice and the double standard of morals.

This year has been published *Human Merchandise: A Study of the International Traffic in Women*,<sup>3</sup> by H. WILSON HARRIS, a book commemorating Josephine Butler. It summarizes the report of the League of Nations referred to previously, and should have a wide appeal, particularly for those who take an interest in the work of the League. One of its objects is to prove that certain national social problems can only be solved by international action. It is a happy incident in the celebration of Josephine Butler's centenary that further testimony should be forthcoming of the good which has sprung from the seed sown by her.

## Scotland.

### Tuberculosis in Scotland.

THE annual report of the Royal Victoria Hospital Tuberculosis Trust, Edinburgh, which has just been issued, describes the work of the Trust in regard to the care and prevention of tuberculosis throughout Scotland and at the Southfield Sanatorium, Liberton, during the past year. One point noted is the great increase in the number of applications for the admission of young children to the colony; this is regarded as a good sign, indicating an appreciation of the fact that tuberculosis is generally implanted in early life. While it is admitted that the claims of persons with advanced tuberculosis must be met, in the interest both of the individual and of the community, it is pointed out that the eradication of tuberculosis would not be achieved by this alone; in the scientific care of the tuberculous child, it is held, lies the sure line of advance, and if this was more thoroughly realized by parents and doctors throughout the country, the depressing procession of tuberculous cripples would disappear in the course of a generation and a half. When a child is received at Southfield Sanatorium Colony the presence of tuberculosis and its extent are defied. Thereafter, by every available means, the child's physiological resistance is raised, and measures are taken to meet particular issues. The production of clean milk is considered an important link in the chain of efforts against tuberculosis, and the Tuberculosis Trust has developed a herd of tubercle-free cattle during the last few years with two objectives—namely, the production of tubercle-free milk and the acquiring of a stock of cows which could be sold as cattle free from tuberculosis. The herd now numbers approximately 100; of these, some 50 are utilized for maintaining the supply of certified milk to a large clientele, which readily takes up all that is available. Of the remainder, about a score would be ready in a year as milk producers for sale to farmers, and the number of cows that would be available would increase year by year. With regard to research, it was the desire of the committee to co-operate as far as possible with tuberculosis care committees. The committee hopes to appoint two special workers for the prosecution of systematic investigation, for which it would be in a position to afford opportunities if an annual sum of £600 could be obtained. During the past year 211 patients had

been admitted to the sanatorium colony from all parts of Scotland. Six additional beds have been rendered available for patients, and the extension of the nurses' quarters has proved of great assistance in administration. The Trust is co-operating closely with tuberculosis committees, and financial grants are made in special cases to assist the families of tuberculous patients. The report is attractively illustrated and contains a reference to the visit paid to the sanatorium colony by members of the British Medical Association during the Annual Meeting at Edinburgh last year. Sir Robert Philip, President of the Association, is vice-president of the Trust, which owes its inception in large measure to his genius.

### Edinburgh Maternity Hospital.

The eighty-third annual meeting of subscribers to the Royal Maternity and Simpson Memorial Hospital, Edinburgh, was held on March 27th. Dr. T. G. Nasmyth, who presided, called attention to some of the chief features in the annual report. The number of patients delivered in the hospital during 1927 had been 2,094, which was the largest number for one year in its history. The institution in its indoor and outdoor work dealt with 38.6 per cent., or more than one-third, of all the births in greater Edinburgh. The ante-natal clinics were growing in popularity and usefulness, and in the past year 10,002 visits were paid to these clinics. During 1927 83 nurses and 287 medical students had been trained. Dr. Nasmyth announced that it had been agreed for financial, administrative, and educational reasons to amalgamate the Maternity Hospital with the Royal Infirmary. The site of George Watson's College, upon which it was proposed to rebuild the hospital, would not be available for some years, and the arrangements for amalgamation were accordingly still in an unsettled state. The hospital must remain under its present management for about six years to come, and the need for support was greater than ever. The income from the fees of pupil nurses had now almost disappeared, because, in common with the other Scottish maternity hospitals, they had to offer free board and training in order to secure the requisite complement of nurses provided with previous hospital training. The deficit on the ordinary working account for the past year had been £3,026, and the hospital had no reserve funds which could stand a repetition of such shortages. If the work was to be continued at its present high standard

of efficiency, a stabilized subscription income of £4,000 per annum must be forthcoming. The adoption of the report was seconded by Mrs. Burnett Smith (Annie S. Swan). Dr. James Haig Ferguson, moving the re-election of the directors, said that the object of the hospital was to provide a maternity service for the eastern counties of Scotland, and this they had to do at present from an undersized, obsolete, and out-of-date building, incapable of adequately overtaking its important function. The fact that the hospital was practically the same in structure as it had been fifty years ago, notwithstanding the greater work done, was not the fault of the directors, but was due to the apathy of the public, which had failed to realize what it ought to do with regard to this institution.

#### Proposed Extension of Galashiels Hospital.

In the annual report of the Galashiels Cottage Hospital recently issued, the necessity for extension of the hospital is urged. Surgical work appears to have increased much in recent years, rendering the present accommodation inadequate both for the number of patients and for administrative requirements. Maternity cases which are likely to be complicated have also been admitted in recent years. Although the hospital was primarily intended for the town of Galashiels and its immediate neighbourhood, a view is now gaining ground that the hospital might serve a larger area, and donations amounting to £3,000 have already been received for the purpose of extension.

#### Glasgow Sick Children's Hospital.

The forty-fifth annual report of the Glasgow Royal Hospital for Sick Children has been recently issued. The number of patients treated in the wards of the hospital was 7,143, while those consulting at the out-patient department numbered 83,591. The average daily number in residence was 244. Ordinary expenditure amounted to £33,294 as compared with £32,108 in the previous year. The country branch of the hospital at Drumchapel, which was inaugurated by a gift of £17,500 from the trustees of the late Mr. Peter Coats, is reported as being still £4,600 short, and the directors make a special appeal for this sum. It is also intimated that a sum of £10,000 is required to provide facilities for research work in the hospital's pathological department.

## Ireland.

#### Royal Victoria Hospital, Belfast.

THE annual meeting of the Royal Victoria Hospital, Belfast, was held in the King Edward VII Memorial Building on March 20th; the Marquess of Dufferin and Ava, chairman of the board of management, presided. The annual report dealt with the amalgamation of the Belfast Maternity Hospital and the Royal Victoria Hospital, and also with the alarming increase of motor accidents; investigation of these cases showed that a large number of the drivers were not insured. The total number of medical and surgical cases admitted into the wards during 1927 was 5,450, of which 202 were cases of motor and bicycle accidents; this did not include a large number of minor accidents treated in the out-patient department. About 50 per cent. of the injured were pedestrians, the majority of whom had been knocked down by motor cars or bicycles; nearly 25 per cent. of the total were motor cyclists. Death had followed in 16 cases. About 50 per cent. of the patients had head injuries, and about 30 per cent. had fractures of the lower extremities, which necessitated prolonged stay in hospital. The number of beds constantly occupied by patients suffering from motor accidents during the year was 17. The estimated cost to the hospital amounted to £1,806, of which only £236 had been recovered to date. The honorary treasurer said the total receipts were £58,646, of which the workpeople's contribution amounted to £20,665. The reduction in the cost of maintenance per bed occupied from £129 to £124 18s. 7d. indicated the economy in management. The adoption of the

report was proposed by the chairman, seconded by the Vice-Chancellor of the Queen's University (Dr. Livingstone), and passed unanimously. Lieut.-Colonel Mitchell, O.B.E., chairman of the medical staff, proposing the adoption of its report, drew attention to the increasing work of the laboratories of the hospital and of the radiological department. The report was seconded by Dr. Rankin and passed. Professor Lindsay proposed the re-election of the honorary treasurer, Dr. Henry Berrington, and of the honorary secretary, Mr. F. A. Heron, and bore testimony to the hard work of both on behalf of the hospital.

#### Dentists Bill in the Free State Senate.

The Irish Free State Dentists Bill was taken in the committee stage in the Senate last week. Its provisions and the discussion which marked its passage in the Dail were outlined on March 17th (p. 465). Sir Edward Coey Bigger, M.D., moved an amendment that in Section 41 the words "Dental Board" be substituted for "Medical Council." Sir Edward said that the section as it stood gave powers to the Medical Council to exercise very important functions in relation to dentistry. He held that the Dental Board should be in a position to make suggestions and also to regulate the curriculum for the qualification of dentists. Mr. O'Farrell said that the proposal in the bill to leave the matters of examinations for dentists and their professional standard in the hands of the Medical Council was illogical and expensive; it placed the Dental Board in a very humiliating position, and he could see no reason for the idea, except that it was a copy of something else. Mr. McGilligan, Minister for Industry and Commerce, said that he had been in touch with the medical profession and the Dental Association, and their views were entirely contrary to those expressed by Sir Edward Bigger. The view of the Dental Association was that it would suit its profession better to leave the matter of education to the Medical Council. Sir Edward Coey Bigger contended that the Minister had not met the points raised. He himself had made it his business to get into touch with two prominent men in the dental profession, who thought that the arrangement proposed by him would be ideal. By twenty-one votes to fourteen the House rejected the amendment. With reference to persons who might feel that they had a claim to be included in one or other of the schedules, the chairman said that these schedules had been referred to a subcommittee to look into the cases listed, and also into certain further applications. The committee had decided to adjourn the matter to allow additional applications to be sent in. Sir Edward Bigger said that the committee had that morning extended the period during which applications could be sent in until April 16th. Further consideration of the committee stage was adjourned, pending the report of the subcommittee.

#### Vaccination in the Free State.

On the motion of Mr. S. Everett (Labour) the Vaccination (Amendment) Bill, 1928, was introduced in the Free State Legislature. This measure, which is a private member's bill, proposes to alter the law governing vaccination by authorizing a statutory declaration of conscientious objection, and amending the Public Health (Ireland) Act, 1879, or Section 7 of the Vaccination Amendment (Ireland) Act, 1879. It gives parents the right to declare within three months from the date of birth of a child that vaccination would be unfavourable to its health. The bill, which received its first reading, gives in the Free State the rights enjoyed by persons in England and Wales.

#### Bangor Sewerage.

Since Bangor, in co. Down, is adjacent to Belfast, and a favourite seaside resort for the inhabitants of that city and of the neighbouring parts of the province, it is with considerable anxiety that statements are received of sewage contamination of the bay and of that of Ballyholme, which adjoins it. The surveyor's report recommends a scheme which will cost some £750,000; but, whatever the outlay, it is generally felt that the sanitation of this beautiful and convenient resort must be made irrefragable.

## England and Wales.

### Royal Sanitary Institute Congress.

THE thirty-ninth congress of the Royal Sanitary Institute, which is to be held at Plymouth from July 16th to 21st, will be attended by delegates from some three hundred societies and sanitary authorities, and by representatives of the universities, Government departments, the dominions, and several foreign countries. Viscount Astor will preside, and the popular lecture will be given by Professor W. E. Dixon of Cambridge. The arrangements follow the usual lines; the congress consists of seven sections, eight conferences will be held, and there will be a health exhibition. In the section of preventive medicine the president is Dr. L. Rajelmann, medical director and secretary of the Health Committee of the League of Nations; Professor Hobday will preside over the section of veterinary hygiene. The remaining sections are devoted respectively to engineering and architecture, maternity and child welfare, personal and domestic hygiene, the hygiene of food, and hygiene in industry, the last-named section having for its president Mr. Ramsay MacDonald. The first conference will comprise representatives of sanitary authorities, the second representatives of port sanitary authorities, and the remaining conferences will be composed of representatives of national health insurance services, medical officers of health, engineers and surveyors, sanitary inspectors, and health visitors. Among subjects on which discussions are being arranged are the tuberculosis problem, immunity methods in scarlet fever and measles, the rheumatic child, and various aspects of national health insurance, including the sickness experienced among insured persons.

### Training and Recruitment of Health Visitors.

The Ministry of Health has issued to local authorities carrying out maternity and child welfare schemes a circular (879) dealing with the position of health visitors, and recalling the decision embodied in Circular 557, to which reference was made on February 21st, 1925 (p. 384). It was announced in the previous circular that on and after April 1st, 1928, the Minister would not approve the appointment of a woman for the first time as a whole-time officer of a local authority with health visiting duties unless she had obtained the new health visitor's certificate. This certificate could only be obtained by women who had attended one of the prescribed courses of training, and by existing health visitors who had completed at least five years' satisfactory service. To facilitate the obtaining of the new certificate by existing health visitors it has now been decided to reduce the qualifying period to three years. The new circular further states that the Minister is anxious that the position of existing health visitors should be fully safeguarded, and that each local authority should pay full regard to the claims of those candidates in making appointments, although they have not obtained the new certificate. Authorities are reminded that the Ministry maintains a list of all health visitors whose appointments have been approved by it, and that local authorities who, in this connexion, desire information should communicate with the department. The remainder of the circular deals with conditions of service, recruitment, and methods of training, which appear to be causing some anxiety. Wide variations exist, and difficulty is being experienced in securing candidates to undergo training owing to the inadequate remuneration offered in many areas; it is therefore feared there may be a shortage. The Minister asks local authorities, when the remuneration of health visitors is under consideration, to give full weight to the fact that new entrants have now to devote three and a half or four years to their training. Reference is made to the conditions of training set out in Memorandum 101/M.C.W. of February, 1925, and alternative methods are described for overcoming the difficulty created by the fact that the expense of undertaking a six months' whole-time course of instruction while earning no salary may have acted as a deterrent to some candidates. In certain areas in which the ordinary full-time six months' course has been provided candidates agree to serve in the

areas for at least six months after obtaining the health visitor's certificate, and receive from the local authority during training an advance of salary, to be repaid during their first six months of service. Further, the Minister is prepared to approve a course of training covering not less than three academic terms, including all necessary subjects and providing for lectures, visits of observation, and practical work. Such a course, it is suggested, could be organized, for example, jointly by a university and a local authority, and the latter body could facilitate attendance by appointing the students, who must be trained nurses with the certificate of the Central Midwives Board, as probationer health visitors, their work, under supervision, being regarded as part of their practical training. They might be paid a salary not exceeding three-quarters that of the ordinary commencing salary of a health visitor. The salaries paid for health visiting would be eligible for grant under the Maternity and Child Welfare Regulations, but, if this was obtained, no grant would be payable in respect of training under Part II of Memorandum 101/M.C.W. Proposals of this kind are invited by the Minister with a view to securing suitable candidates who could not otherwise enter.

### Small-pox among Casuals.

The Minister of Health has been advised that it will be necessary to maintain the arrangements described in his circular (859), to which we referred on January 28th (p. 154), for the detection of small-pox among casuals. A further circular (880) has therefore been addressed to boards of guardians in England and Wales directing that medical officers shall continue to examine all casuals admitted from April 1st to June 30th with a view to detecting cases of small-pox. The circular states that if the procedure already outlined is observed it should not be necessary to keep casual wards closed after adequate disinfection has been carried out. Their prolonged closure, it is suggested, may lead to the dispersal of casuals in other places and to the spread of small-pox. Guardians are also reminded that the powers conferred on them to detain persons suffering from infectious disease do not extend to persons who, though they may have been exposed to infection, are not actually suffering from disease. There is, therefore, no power to detain such persons beyond the prescribed period of two nights, even though they have declined to be vaccinated.

## Correspondence.

### HEAT CRAMP.

SIR,—I was much interested in the description by Dr. Rayner Thrower in the *British Medical Journal* of March 31st, p. 546, of cases of acute cramp occurring, not among stokers or miners working in hot atmospheres, but among men working in the engine-room of a motor ship. From Dr. Thrower's description, however, I can entertain little doubt that the cause of the cramp is the same—namely, acute poisoning by water.

When we say that the "osmotic pressure" of the blood must be kept constant what we really mean, as I have several times pointed out, is that the diffusion pressure of water, just like the diffusion pressures of many other substances, must be kept constant. This pressure depends on the relative concentrations of water molecules and other molecules, and, in the case of the blood, more particularly on the concentrations of sodium chloride. The kidneys are constantly engaged in regulating this "osmotic pressure," but in the case of men engaged in pretty heavy muscular exertion they are almost completely thrown out of action, as was very clearly shown a few years ago by Dr. Pembrey and his associates.

Now a man who is both sweating hard and working hard, and is at the same time drinking water to relieve his thirst, is losing chloride rapidly in his sweat and at the same time replacing the sweat, which contains about a quarter per cent. of sodium chloride, by practically pure water. The kidneys at the same time are out of action, so cannot deal with the excess diffusion pressure of water. The result is acute rise in the diffusion pressure of water or fall in the

"osmotic pressure"; and violent attacks of cramp are symptomatic of this.

The whole subject has for some years past been occupying part of the attention of the Birmingham University Mining Research Laboratory, of which I am director. Professor Moss discovered the existence of heat cramp among miners. When a miner, who had already had an attack, was examined underground by my son, Mr. J. B. S. Haldane, he found, first, that only a few cubic centimetres of urine had been secreted during the whole shift, and secondly, that this urine contained not the smallest demonstrable trace of chloride. There was thus acute shortage of chloride.

Perhaps few persons realize how much sweat, and therefore how much chloride, a man who is thoroughly acclimatized to heat may lose in a short time. Professor Moss found that a thoroughly acclimatized miner from hot workings lost, in the experimental hot chamber, as much as 6½ lb. an hour, though the sweating of an unacclimatized man is feeble in comparison.—I am, etc.,

Oxford, March 31st.

J. S. HALDANE, M.D., F.R.S.

#### GLAND GRAFTING AND INHERITANCE.

SIR,—The letter of Surgeon Rear-Admiral Charles M. Beadnell in your issue of March 31st (p. 570) is clearly written under a complete misapprehension of the nature of the various testicle-grafting operations.

He is under the impression that any offspring sired by the grafted animal after the grafting are descended from spermatozoa derived from the foreign testicle which has been implanted. This is definitely not so. Neither in Voronoff's operation nor in the operations of Steinach, Lichtenstern, Mühsam, or any of the other workers in this field has it been found possible to bring the graft in such a relation to the testicle itself, or to the vas deferens, that spermatozoa from the graft could be emitted in the animal's semen. Nor has it yet been found possible to maintain the graft in such a condition that it will continue to produce spermatozoa in its new position. Microscopic examination of grafted testicular tissue, at intervals after its transplantation, show clearly that the spermatogenic tissue degenerates, and sperm cells are no longer produced.

Thus, since (1) the graft ceases to produce sperm cells, and (2) even if sperm cells were produced by the graft they could not find their way into the semen, there can be no question of the future offspring of the grafted animal being descended from the gametes contained in the graft.

It is curious that the medical profession in this country seems to know so little about the technique and results of the various so-called "rejuvenation" operations which are more widely practised elsewhere. It is very desirable that some exact observations should be made under strict test conditions, first in laboratories and then in hospitals. In the meantime, those of us who have carried out the operations in a considerable number of cases are convinced that if one chooses one's cases wisely one often does get remarkable results. And it is important to emphasize the fact that the improvement which often follows the operation is not exclusively, or even predominantly, sexual.—I am, etc.,

London, W.1, March 30th.

NORMAN HAIRE, Ch.M., M.B.

#### MINIMAL RISES OF TEMPERATURE IN RHEUMATOID ARTHRITIS.

SIR,—Dr. L. Schmidt is to be congratulated on his timely article in your issue of March 24th (p. 493) advocating rest and feeding in those cases of rheumatoid arthritis in which the temperature is unstable. Any form of movement involving the affected joints he regards as provocative of auto-inoculation. It is difficult to improve on the clarity of his words:

"The important point is the entry of substances foreign to the body, or at least to the joints, into the joints and the surrounding tissues in such amounts that the irritation set up leads to various degrees of inflammation and their sequels. The joint tissues and the surrounding tissues are thus toxic, whether they take the form of macroscopic or merely of microscopic exudates and chemotactic combinations. Absorption of such substances has, according to this view, the same significance as an auto-inoculation."

Long-standing fallacies notoriously die hard. One of the worst is embodied in the idea that to prevent permanent stiffness patients must be kept moving. Every medical student knows that inflammation has to be treated by rest, and yet continually this universal rule is broken or is disregarded in the case of arthritis. Personally I would go much further than Dr. Schmidt, and would urge that the treatment of rest advocated by him should not be confined to cases in which a general intoxication is present, but that in all arthritides treatment should be begun by reducing the voluntary movements of those joints showing active disease. The amount of movement to be permitted is largely a matter of experience, but it is always better to be on the safe side, and even a period of complete immobilization of one or more joints is preferable to permanent disablement.

The governing factor in all cases should not be the prevention of disease, but the control of auto-inoculation. Fortunately in the majority of cases auto-inoculations are not sufficiently marked to prevent gentle movements of some kind. Thus, for example, even febrile cases at rest in bed may often be permitted to move their lower limbs once or twice a day—a very different proposition from continually walking about on them. The difficulty is that in so many mild degrees of arthritis, particularly osteoarthritis attacking one joint, patients can seldom be persuaded to give up their activities. Yet, when through some intercurrent illness these activities are forcibly curtailed, it is invariably found that the pain in the affected joint has lessened or even disappeared.

In every case of arthritis, from the mildest to the most severe, treatment should be directed toward reducing the active movements in affected joints, more especially in those of the lower limbs. In some cases no measures short of complete immobility will prevent auto-inoculation. In these, after a period, experiments can be made first with very slight passive movements, and then with more energetic voluntary movements, in order to find that degree of activity which the patient can undertake without provoking auto-inoculations or increasing the local inflammatory changes. The former would be shown by malaise, pain in other joints, or even in a rise of temperature; the latter by pain in and around the joint itself. If these principles were more generally recognized and universally applied, there is little doubt that the crippling results of arthritis would be less in evidence.—I am, etc.,

London, W.1, March 29th.

H. WARREN CROWE.

#### DYSPHAGIA ASSOCIATED WITH ANAEMIA.

SIR,—In your issue of March 24th Dr. A. F. Hurst takes exception to my statement that the closure of the lower end of the gullet in cardiospasm is always firmer than normal, and that sometimes it is so great that it yields only to prolonged steady pressure. He maintains that "anybody who has passed a mercury tube in such a case must have been struck by the remarkable absence of resistance offered by the sphincter, and by the absence of any grip upon it when it is withdrawn from the stomach."

Dr. Hurst naturally contests my statement, for, if true, the old-established view that the disease in question is cardiospasm receives further confirmation, while that as to achalasia is confuted.

It is self-evident that a more exact estimate of the degree of resistance at the lower end of the gullet can be made by the gradual introduction of an oesophagoscope under visual control while the patient is recumbent and anaesthetized, as is my practice, than by passing blindly, or with the assistance of x rays, a mercury tube, as recommended by Dr. Hurst. All of my cases, excepting a few of the earliest, have been carefully examined with reference to the tendency of the cardiac canal to undergo spasmodic contraction, and as to the degree of resistance offered by this contraction. Resistance greater than the normal has been encountered in all cases, and active spasm has been seen in nearly all cases.

Dr. Hurst employs rubber tubes of various sizes, each containing 1 lb. 5 oz. of mercury. If one of these weighty instruments passes through the lower end of the oesophagus—which has no anatomical sphincter and where the muscular

fibres are unstripped—he accepts this as proof of the absence of spasm. He considers that if spasm did exist there would be resistance such as the anal sphincter in a state of spasm offers to the introduction of the finger. Surely an inappropriate comparison.

Turning for a moment to the upper end of the oesophagus. When this is inspected in the manner above described in cases of the same nature as those which formed the subject of the paper by Mr. Mason Jones and Mr. R. D. Owen I have invariably found such firm closure that any other diagnosis than spasm was inadmissible. I do not deny that in some of these patients the muscles concerned in projecting the food into the oesophagus may have been weak and possibly parietic; or that spasm of the crico-pharyngeus extending over a period of years occasionally gave rise to an appearance resembling a circular membranous stenosis, but which was shown to be due to the spasm.<sup>1</sup> Paresis or achalasia of the crico-pharyngeus itself certainly did not exist.

The only other important reason advanced by Dr. Hurst in support of his recommendation to substitute the term "achalasia of the cardia" for the term "cardiospasm" is that in the disease in question "hypertrophy of the cardiac sphincter is never observed after death, even if the obstruction has lasted twenty or more years, although long-continued spasm would necessarily lead to hypertrophy." In reply to this objection I need merely point to the published drawings and descriptions of specimens in which more or less of the terminal portion of the oesophagus or "cardiac sphincter" has undergone hypertrophy.<sup>2</sup> My patient was aged 21 years and Dr. Cameron's was 6 years. In both of these young subjects there was pronounced hypertrophy in the wall of the cardiac canal. From remarks made by the late Professor Shattock in this connexion one is led to inquire whether this hypertrophy does not exist in many of the cases at a stage earlier than that when usually examined *post mortem*, and whether the degenerative changes in the muscular coats so frequently reported may not cause muscle which at one time was hypertrophied to appear of normal or diminished thickness.

The theory of achalasia is based upon three negative conditions—namely, absence of sense of obstruction at the cardia on passing the mercury tube, absence of grip by the sphincter so that the mercury tube is easily withdrawn, and absence of cardiac hypertrophy. In this letter I have shown that more exact methods of observation and an acquaintance with the recent literature of the subject go to prove that the conditions which Dr. Hurst denies in reality exist.—I am, etc.,

Glasgow, March 28th.

A. BROWN KELLY.

### THE "CURE" OF PULMONARY TUBERCULOSIS.

SIR,—Many of your correspondents seem to be very sceptical as to the possibility of the "cure" of advanced cases of pulmonary tuberculosis. If by "cure" is meant the restoration of destroyed tissues it is, of course, impossible, but if it means the restoration of the patient to health in spite of more or less seriously damaged lungs, with the disappearance of cough and sputum, this has, of course, been done in numerous instances. The method used is the complete immunization of the patient with tuberculin (H.T.S.) and autogenous antigens made from the enterrh-producing microbes found in the sputum. Before the war I demonstrated a series of these cases to a special investigator sent by the Medical Research Council. The patients shown are alive and well now. At the Bradford Meeting I showed a series of charts and radiograms of such arrested cases.

Some years ago Dr. Maguire, medical insurance commissioner, examined a series of these advanced arrested cases, all of them with unquestionable evidence of arrested disease. Dr. Maguire made a report to his commission, who forwarded it to the Government department concerned. Messrs. Hewlett, who are agents for my tuber-

culin, have demonstrated x-ray photographs before and after treatment at several medical exhibitions. These patients are alive, well, and are not infectious, but parts of their lungs are destroyed and replaced by fibrous tissue, and in many their hearts are displaced by the contraction of this fibrous tissue—one who is perfectly well and active to such an extent that the "apex beat" is in the right axillary line.

Early cases can be restored to such an extent that no evidence of disease can be discovered by physical examination, and are therefore useless for demonstration purposes to the sceptic who invariably suggests an error in diagnosis. Except in one exceptional case of acute lobar pneumonia phthisis with massive consolidation and no sputum, the diagnosis in which was made by the response to tuberculin (H.T.S.), all cases in which I claim arrest and cure have had acid-fast tubercle bacilli in their sputum. I have enabled many general practitioners to cure patients, and I hope to see every practitioner treating his own patients; he will give them a far better chance of recovery—indeed, in advanced cases, their only chance of recovery.

Tuberculin by itself will produce an increased percentage of cures, but nothing like the percentage of cures produced if complete antigens are used. Tuberculin cannot be expected to induce antibodies against virulent streptococci. May I say again, however, that tuberculosis will not be stamped out or reduced to reasonable proportions by the treatment, however effective, of advanced cases? Normal natural immunity will protect against the tubercle bacillus, as is evident by the survival of the majority of us. This normal immunity can be assured by a few inoculations with a potent tuberculin. I assure members of families in which tuberculosis has occurred that they will not develop the disease if they receive these inoculations; I have been practising this for over twenty years and I have yet to meet with a failure.

Finally, I would say to the opponents of tuberculin that, like strychnine, it is a potent drug, and must be used in proper dosage. It is easy to kill any patient with strychnine, it is easy to kill a tuberculous patient with overdoses of tuberculin; but no physician kills patients with strychnine, and no patient is killed by tuberculin given in proper doses.—I am, etc.,

University College, Dublin, March 26th.

W. M. CROFTON.

### EFFICACY OF TUBERCULIN.

SIR,—With regard to the efficacy of tuberculin I have been long convinced that one of the chief obstacles to a conclusion on a sound scientific basis has been the absence of proper "controls." Enthusiasts commonly adduce a series of cases treated successfully by tuberculin, but do not contrast these results with the results of treatment of a similar series of cases without tuberculin. Tuberculosis, in the early stage, is a disease from which complete recovery will spontaneously occur in a fair proportion of cases if reasonable precautions are taken. The necessity, therefore, of proper "controls" is obvious if we are to avoid the old fallacy of arguing *post hoc, ergo propter hoc*.

Where an effort has been made to conduct an investigation with such "controls"—as, for instance, in that of Dr. Noel Bardswell at King Edward VII Sanatorium, Midhurst (*Preliminary Report on the Treatment of Pulmonary Tuberculosis with Tuberculin*, H. K. Lewis, 1914)—the result has been to discredit tuberculin. In a prefatory note to this report Professor Karl Pearson states: "If it were possible the scientific method would be to select patients suitable for tuberculin treatment, treat only those whose surnames began with A to K, and then compare the results with simple sanatorium treatment of the remainder, L to Z, of these selected patients. Thus in two or three years we should know exactly the value of the treatment. When all selected cases are treated as at present we shall have no suitable control to determine whether the treatment has any real value, unless, indeed, we again leave it off."

My own experience of tuberculin goes back to 1912, when tuberculosis officers in many areas were almost under compulsion to give tuberculin. Patients received injections twice a week, provided they could be taught how to keep

<sup>1</sup> See Dan McKenzie's paper, "Post-ericoid spasmodic stricture," *Journ. Laryngol., Rhinol., and Otol.*, 1918, p. 270, and author's paper, *ibid.*, 1919, p. 285.

<sup>2</sup> See Irwin Moore's papers in *Journ. Laryngol., and Otol.*, 1927, p. 577, and *Proc. Roy. Soc. Med.*, vol. xii, Sect. Laryngol., p. 67; author's case, *ibid.*, vol. xiii, Sect. Laryngol., p. 206; and J. A. M. Cameron's case, *Arch. of Dis. in Childhood*, vol. ii, p. 358.

a temperature chart efficiently. I also had patients under treatment at sanatoriums, where the effects of treatment could be more closely observed. My experience was that the cases which appeared to do well with tuberculin were precisely those cases which would be expected to do well under any treatment (sanatorium or otherwise)—namely, the cases where the disease appeared to be in the incipient stage, for the most part "ambulant afebrile cases," or those in which there was a possibility that no active tuberculosis was really present, tubercle bacilli never having been demonstrated. This draws attention to the necessity in any scientific investigation of dealing separately with cases in which tubercle bacilli have been demonstrated and those in which they have never been found. On the other hand, I have records of cases in which tuberculin appeared to aggravate the disease, and in which the condition improved (as shown by temperature chart, weight, and the feelings of the patient with regard to lassitude, appetite, etc.) on the discontinuance of tuberculin. As regards the less favourable type of case, I unhesitatingly echo the words of Dr. Bardswell: "Tuberculin cannot be looked upon as a means whereby an unfavourable case can be converted into a favourable one, or as likely to turn the scale in a patient's favour when his progress is doubtful." The method of administration was that of slight reactions, and I have confined my remarks to pulmonary tuberculosis.

Is it not taking a very sanguine view to expect that one of the first outstanding successes of vaccine treatment should be with such a widespread and intractable disease as tuberculosis? What real scientific basis is there for the belief in the efficacy of vaccines in therapeutics? All the unequivocal successes with vaccines have been not with the cure of existent disease, but with the protection of the healthy individual against disease; its great victories have been won not in therapy, but in prophylaxis. Professor J. C. G. Ledingham (*British Medical Journal*, May 8th and 15th, 1926) gives reasons for doubting the specific action of vaccines in vaccine therapy. Furunculosis, for example, may respond as well to a vaccine prepared from *B. coli communis* or *B. typhosus* as to a staphylococcal vaccine. The temperature in typhoid fever has been promptly reduced by an intravenous injection of typhoid vaccine; but it was found that an injection of *B. coli communis* vaccine, or even less specific substances such as casein or albumose, could produce the same effect. On the other hand, in vaccine prophylaxis, he points out, the vaccine must be of true specificity. The one stands on a sure scientific basis, the other on a shifting foundation of conflicting clinical testimony. If, then, we look to tuberculin as a weapon against the tubercle bacillus, we should expect to find it successful—if at all—as a prophylactic rather than as a therapeutic remedy. The hitherto unequivocal success of bacteriology in therapeutics has been not with vaccines, but with serums, and unfortunately so far there seems to be small hope of finding an antituberculous serum, nor is the disease one that lends itself to such hope.—I am, etc.,

Clifton, Bristol, March 23rd.

E. WEATHERHEAD.

#### MIDWIVES AND ANTE-NATAL WORK.

SIR,—I have read with interest the letters of Professor A. Louise Mellroy and Dr. Malcolm Donaldson (March 17th, p. 466, and March 24th, p. 520, respectively). That ante-natal work is still in its very infancy is only too sad a fact. Meetings to "discuss" maternal morbidity and maternal mortality seem to be held almost daily, but "discussions and resolutions" seem to be as far as they proceed. Having, until almost a year ago, been for between two and three years in charge of the obstetrical and gynaecological wards of a large and modern Poor Law institution, I have been appalled—sometimes I have been almost terrified—by the so-called midwives one meets in general practice. To suggest that more than a very small percentage of them can give proper ante-natal supervision is absurd. Many of the old myths and superstitions of the dark ages of midwifery still persist in their midst. Their chief aim seems to be triumphantly to inform the practitioner on his arrival as to the state of the os uteri—whether the patient be in labour or not—and for this information they appear to expect a certain amount of

praise and admiration. The whole system appears archaic. That admirable body the Central Midwives Board to my mind must continue to strive to provide the mothers—and future mothers—of Britain with a body of more efficient and less meddlesome midwives. Many of those at present in practice could elicit as much information from the palpation, etc., of a straw-stuffed sack as from the palpation of a pregnant abdomen nearing full term.

But is the midwife entirely to blame? Two abnormal conditions that can be avoided have come to my notice more often than one would expect; and they are: (1) eclampsia—a practitioner, not yet middle-aged, informed me that he had about six or eight "unavoidable" cases of this almost historical condition in his practice each year; and (2) breech presentations in primiparae. A still very large percentage of these cases occur with, in many cases, fatal results to an otherwise healthy infant. The practitioner is not to blame; he must undertake midwifery, or else his practice will suffer financially.

Queen Mary has recently expressed the hope that in the near future the figures for maternal morbidity and maternal mortality would show a marked decrease. This hope can only be fulfilled when maternity work comes much more under the jurisdiction of obstetrical and gynaecological specialists in maternity hospitals, maternity homes, or, where circumstances permit, in the patients' homes. It seems a pity that obstetrics has not shown the same progress as surgery since the days of that pioneer, Sir James Y. Simpson.—I am, etc.,

London, N.2, March 26th.

IAN S. ROBERTSON-BAIN.

#### SUPERANNUATION OF MEDICAL OFFICERS OF HEALTH.

SIR,—The article on page 511 of your issue of March 24th about the report of the Departmental Committee on the Superannuation of Local Government Officers offers cold comfort to medical officers of health serving those authorities which have not yet adopted the Local Government and other Officers' Superannuation Act, 1922. As shown on page 559 of the November, 1927, issue of *The Local Government Service*, the official organ of the National Association of Local Government Officers, only 16,962 (that is, 2.89 per cent.) of the total number of public officers in the country remain unprovided for by superannuation schemes.

The departmental report has been over two years under the consideration of the committee, and it is now quite time all medical officers of health were placed on an equal footing in respect of superannuation, especially seeing that the report recommends compulsion being applied to any recalcitrant local authorities. Junior medical officers can leave their posts to obtain these benefits elsewhere, but the seniors must stay where they are. Cannot the Parliamentary Medical Committee see its way to take early action on their behalf? Otherwise elderly medical officers must continue in office, even though they may become physically incapacitated, whilst the more capable juniors continue to avoid entering the service of the less progressive local authorities, the public welfare in these areas being thereby doubly handicapped.—I am, etc.,

March 26th.

A VETERAN M.O.H.

#### SALARIES OF MEDICAL WOMEN.

SIR,—I have noticed with much concern the extremely small salaries which lady colleagues in the medical profession have to content themselves with when undertaking assistantships to doctors in general practice.

For some time past I have known that well-qualified women doctors are willing to act as assistants for £3 or less per week, but until lately I did not know that they are willing to go as assistants for their board only—without any salary. I have obtained this information from an unquestionably reliable source.

Such a condition of affairs must react unfavourably upon the whole profession, and the first to suffer will be the male members of the public health service. The matter is one which should receive the early consideration of the Society of Medical Officers of Health and the British Medical Association.—I am, etc.,

March 27th.

COUNTY MEDICAL OFFICER.

## Obituary.

HENRY LAWRENCE McKISACK, M.D., F.R.C.P.,

Consulting Physician to the Royal Victoria Hospital,  
Belfast.

We have to announce with much regret the death of Dr. H. L. McKisack, on March 26th, after a short illness, supervening on some months of impaired health. His loss will be deeply felt throughout the medical profession in Northern Ireland.

Henry Lawrence McKisack was a native of Antrim, and was born at Carrickfergus in 1859. His school days were spent at Holywood and Broadstairs, and he was for some years a student at the Royal Academical Institution. After engaging in business for a short time he entered the medical department of Queen's College, Belfast, and graduated in the old Royal University of Ireland as M.B., M.Ch., M.A.O. with honours in 1887. He proceeded M.D. in 1890, obtained the diploma M.R.C.P.Lond. in 1904, and was elected F.R.C.P. in 1916. Among the important posts in Belfast which he held were those of visiting physician to the Royal Victoria Hospital and the Ulster Hospital for Women and Children. He later became consulting physician to these hospitals and also to His Majesty's Forces in Northern Ireland and to the civil service. Dr. McKisack held the appointment of clinical lecturer at Queen's University, Belfast, and had been an examiner in medicine at Trinity College, Dublin. He was a past president of the Ulster Medical Society, and served as president of the Ulster Branch of the British Medical Association in 1914-15, and he was one of the original members of the Association of Physicians of Great Britain and Ireland.

Dr. McKisack contributed numerous clinical articles to medical periodicals, including one on atypical exophthalmic goitre which appeared in the *British Medical Journal* in 1913. His principal work, a *Dictionary of Medical Diagnosis*, was published in the autumn of 1907. Although arranged on the alphabetical system, this useful and clearly written book was informed throughout by a definite purpose—to help the student to acquire the habit of approaching every case with an open mind and refusing to form an opinion until he has observed and reflected upon all the signs and symptoms. Among its best articles were those on physical signs in the lungs and heart. He also published, in 1912, a smaller book entitled *Systematic Case-taking*. Both works passed into a second edition.

A colleague writes: No more popular medical man than McKisack has lived in Ulster. He had the capacity of impressing his impartiality on others, and of enabling them to see both sides of a question. Everyone knew that he was both clear-sighted and upright, and so could be absolutely trusted. He inspired confidence and affection in his patients and colleagues. He is survived by a son and daughter, with whom much sympathy is felt. His elder son was killed in the Flying Corps during the war, and Mrs. McKisack died about a year ago.

HUGH PLAYFAIR, M.D., F.R.C.P., F.R.C.S.,

Consulting Obstetric Surgeon, King's College Hospital, London.

We announced last week the death, on March 25th, of Dr. Hugh Playfair, who was for many years obstetric and gynaecological surgeon to King's College Hospital, and a well-known figure in the medical world of London.

Hugh James Moore Playfair was born in 1864 at Edinburgh. His father was General Archibald Playfair, and he was a cousin of the late William Smoult Playfair, M.D., LL.D. (1835-1903), obstetric surgeon to King's College Hospital, in whose footsteps he followed. W. S. Playfair had been one of the first obstetricians in this country to insist on doing his own abdominal operations instead of handing them over to a general surgeon. From Fettes College Hugh Playfair went to King's College, London, and while studying medicine served as dresser in Lord Lister's wards in the old building of King's College Hospital. He obtained the M.R.C.S., L.R.C.P. diplomas and the degree of M.B.Lond. in 1890, and after a period of study in Germany proceeded M.D. in 1892. He then held

in succession at King's the posts of resident accoucheur, obstetric tutor, assistant obstetric surgeon, and lecturer on practical obstetrics. He obtained the diploma of M.R.C.P.Lond. in 1896, the F.R.C.S.Eng. in 1899, and was elected F.R.C.P. in 1918. For some years Playfair held the appointments of assistant physician to the Royal Waterloo Hospital for Women and Children and gynaecological surgeon to the Metropolitan Hospital, relinquishing them when he was elected to the full staff at his own hospital. He was an able and lucid teacher, and extremely popular with all his students. On his retirement from active work at King's College Hospital three years ago, owing to impaired health, he was elected consulting obstetric surgeon. He had served as examiner in midwifery and diseases of women for the English Conjoint Board, was consultant to a number of cottage hospitals in towns near London, and enjoyed for many years a considerable private practice.

We are indebted to Sir G. LENTHAL CHEATLE, K.C.B., F.R.C.S., for the following personal appreciation:

It is a sad, respectful custom which ordains that those of us who are left behind should publicly state our impressions of our friends and colleagues who have recently passed away. I recognize the inadequacy of my attempt to treat thus the memory of Dr. Hugh Playfair. With deep regret his colleagues, students, and friends learned that ill health necessitated retirement from our midst. It was with profound grief we heard that our hopes and desires for his recovery in the quiet, happy, and picturesque home that had been planned by Mrs. Playfair and him, had all been in vain. Our friendship began when I was house-physician at King's College Hospital and he was one of my clerks. I recognized his ability, and entrusted him with many duties that were additional to his official work. In those early days Playfair had already determined to specialize in gynaecology and obstetrics; with that object in view he began to study for the F.R.C.S.Eng. as well as for the M.D.Lond. Although he was a clerk to Lord Lister he never became house-surgeon; he limited his house appointments to those intimately bearing upon the work of his life. In the early times of our professional careers Hugh Playfair and I occasionally visited the clinics and towns of interest in Europe. He was an ideal companion, and he kept the eye of a skilled financier on our expenditure without stinting our enjoyment. In many cities we scoured the shops of dealers in "antiques." In one of these establishments we were pestered by a dealer whose goods we did not consider were as genuine as he tried to make us believe. While he had disappeared to the back of his premises in search of more convincing "pieces" we took the opportunity of making a rapid exit and decamped. Feeling that we had skilfully solved an embarrassing situation we hastened into a similar shop two or three doors away, to continue our hunt and partly to bide ourselves. While thus engaged we failed to notice the attendant of our inspection. At last we turned our attention to him, and were horrified to see the same person whom we had just evaded; he owned both premises. While antique hunting in Milan Playfair unearthed a type of picture he was then collecting. The picture is in his collection. Playfair's instinct for attaining his object was so intense that he failed to notice the incidence of a small earthquake, which sent the owner of the shop and me into the street in great alarm. On our return we discovered Playfair still expostulating with the assistant upon the enormity of the sum demanded for the picture. Neither of them had been aware of the earthquake.

Our busy lives necessitated a loss of touch with each other, yet in the nature of things my family and I reaped the benefit of his friendship and skill, the value of which I can never repay. Playfair loved his home, his profession, art, and all his fellow creatures. His guests must have been struck by their host's taste in art as well as in hospitality. His knowledge, appreciation, and judgement in selection were always increasing his art collection and beautifying his home. The love he bore his fellow creatures was reciprocated by all those with whom he came in professional or friendly contact. We are all sure that he passed a happy life as well as a successful one. Playfair's death leaves a gap in our lives that can never be filled.

**JAMES BUCHANAN YOUNG, M.B., D.Sc., F.R.S.Ed.,**  
Formerly Lecturer on Public Health, University of  
Edinburgh.

THE death took place suddenly, on March 17th, of Dr. James B. Young at his residence, Dalveen, Liberton, Edinburgh. Dr. Young had for many years been lecturer in public health at the University of Edinburgh, and was well known to many generations of medical students.

James Buchanan Young was born in 1866, and took the medical course at the University of Edinburgh, where he graduated M.B., C.M. in 1890. Determining from the first to devote himself to public health, he took the B.Sc. degree in that department in 1892, and in the following year became a Doctor of Science in Public Health. In 1892 he became assistant to the late Sir Douglas MacLagan in the department of forensic medicine, which at that time included the teaching of public health, and he continued in this capacity as assistant to Sir Henry Littlejohn when the latter succeeded to the combined chair in 1897. In the following year the subjects of forensic medicine and public health were separated, and when, in 1898, Professor Hunter Stewart was appointed to the chair of public health Dr. Young became his assistant. In 1902 the Usher Institute in Public Health was established in Warrender Park Road, and upon Dr. Young, as assistant to the professor, fell a very large share in the organization of this institute. The important work of reporting upon clinical material examined at the institute in connexion with the public health work of the city devolved upon Dr. Young, and in this matter he rendered for many years invaluable help to the city and to the practitioners of Edinburgh. In the laboratories a great part of the teaching of the large number of medical students passing through the department of public health, as well as of graduates taking a practical course for the B.Sc. degree, was done by Dr. Young. Many students who graduated through a period of thirty years will remember with gratitude his helpfulness, kindness, and devotion to duty. In 1921 his long period of service as an assistant was recognized by his appointment as the first lecturer in public health in the University of Edinburgh, and he continued work in this capacity to the time of his death.

As a Fellow of the Royal Society of Edinburgh he took much interest in the work of this society, and made numerous contributions to it, such as an account of "A new apparatus for counting bacteriological colonies in roll cultures," communicated in 1893, and on "Chemical and bacteriological examination of soil," with special reference to the soil of graveyards.

The interment took place at the Grange Cemetery, Edinburgh, on March 20th, and was attended by a large number of representatives of the medical profession.

**WILLIAM MUIR SMITH, M.B., C.M.,**  
Eastbourne.

WE regret to record the sudden death from heart failure, on March 26th, of Dr. William Muir Smith. He was born at Irvine, in Ayrshire, in 1861, and graduated at Glasgow University as M.B., C.M. in 1884. After qualifying he went as assistant to Dr. Wilson at Crewe, and from there to a practice in the country, at Bourton-on-the-Water in Gloucestershire. There he led the hard life of a country general practitioner, and in those days, before the arrival of the motor car, did much of his work in the saddle. His spare time was occupied in hunting, for he was a lover of horses. He had by this time married, and, as his family was increasing, he sold his practice at Bourton and proceeded to Eastbourne in 1893, and lived there until the time of his death. He soon acquired a large practice in Eastbourne, but being a man of tireless energy and restless spirit entered into many other activities. He was a keen politician, an enthusiastic Liberal, and a forceful platform speaker. For many years he actively supported the Liberal candidates, and was engaged in the work as chairman or vice-president of the local Liberal Association. He was appointed a justice of the peace in 1906, and as magistrate appeared on the bench whenever time would permit. A true Scotsman, he was a prominent member

of the local Scottish Association, and had the honour of proposing the "Immortal Memory" at the Burns Night dinner, an oration which subsequently was printed in pamphlet form. He was a Presbyterian and an elder of the Church. He was a life vice-president of the Amateur Football Association, and for very many years an active member of the Eastbourne Cricket and Football Club, and chairman of the Eastbourne Football Club for twenty-five years. He always took a keen and active interest in medical politics. In the early nineties there was much friction between the friendly societies and the medical profession; and so in 1895 there was started the Eastbourne Provident Medical Association. This was a "club" by which the members obtained medical treatment on payment of a small weekly sum, but which was controlled and administered by the doctors themselves. Muir Smith was largely instrumental in founding this provident association. It was one of the first started in the country, and is still flourishing to-day. He was actively connected with national health insurance work from its inception, and was secretary of the Local Medical and Panel Committee until the time of his death. His most active public interest was the work of the British Medical Association. It was only last year that his twenty-first year as secretary of the Eastbourne Division was completed, and the occasion was honoured by the presence of Dr. Alfred Cox at the annual meeting and dinner of the Division. Muir Smith never missed a meeting, and was the representative of the Division at the . . . of the Association for many years. . . these activities he conducted a large general practice, and was clinical tuberculosis officer to the borough of Eastbourne, with charge of the tuberculosis hospital. A man of decided and fearless opinions, final in his judgement, a somewhat curt and outspoken manner concealed a generous and warm heart. He never spared himself, and did his utmost in other people's interests; none came to him in vain for help or advice. For the past two-years his health had been failing, but he continued with his work. He leaves a widow, five sons, and one daughter.

THE MEDICAL SECRETARY writes: The above notice gives a very good idea of Muir Smith's activities, and it says truly that his main interest outside his practice was the British Medical Association. It has been my good fortune to come into contact with many men for whom the Association was a real hobby to which they gave much time and interest, and a few men for whom it was the object of something approaching devotion. Muir Smith belonged to the latter select few, and during the course of my long friendship with him I received much advice, frequent remonstrances, more in sorrow than in anger, when he thought we were not strong enough at headquarters, but always devoted co-operation. He was absolutely fearless, and conscientious to an extent which his colleagues at Eastbourne must sometimes have found rather trying, but they never questioned his honesty, his knowledge of his subject, or his intense desire to serve his profession. In 1926, writing to ask me if I would attend the annual meeting which would celebrate his twenty-first year of office as secretary, he said:

"By that time I will have completed my twenty-one consecutive years as honorary secretary. I know the members will not entertain the idea of my resigning without some better reason than advancing years, but I feel that I have served my day and generation (with credit, I hope) long enough, and I am keeping someone of the rising generation from taking active participation in the work of the Division and getting initiated into the duties of the position before I am called hence; and lest I might depart of a sudden it is my duty to resign. Again, as the members do not worry about medical politics so long as I am at the head of affairs I feel that the present one-man administration is inimical to the enterprise of the Division in working out its future salvation in this direction. Not that my interest in the work of my office, in the betterment of the profession, or politics in general, is abated in its keenness one jot or tittle from thirty years ago. During all this long period I have not been absent from a single meeting of the Division or executive; I have been representative at the Representative Body twelve annual meetings; on Branch Council ever since the Branch was formed; past-president Sussex Branch; second chairman of the Division; honorary secretary of Local Medical and Panel Committee ever since formed; attended every conference of representatives of Local Medical and Panel Committees ever since instituted; served on Insurance Committee ever since set up, etc.—all of which, I think, constitutes a bit of a record."

It is sad to think that his presentiment that he might die suddenly while still holding office has proved true, but I cannot help feeling glad that he retained to the last an office of which he was so very proud. The Association can have had few more loyal or more devoted servants than Muir Smith.

Dr. A. DEANE writes: By the death of Dr. Muir Smith his colleagues in Eastbourne have lost a most sincere and indefatigable worker on their behalf. As secretary of the Eastbourne Division for twenty-one years, and of the Panel Committee since its commencement, he has done extraordinarily keen and strenuous work, much of which has been carried out in the small hours of the morning. His loyalty to his profession and strong integrity of character won the deepest respect and regard from his colleagues, to whom he was ready to give his help without stint of time or trouble. He was a staunch fighter on controversial subjects, and ever with a sense of fairness and justice. His self-sacrificing work on behalf of his profession, added to that of a very busy practice, must have been a great strain on his health. His keen and vivacious presence will be sadly missed by his fellow practitioners, who as members of the Association gratefully recognize the immense work he has done for this Branch.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE Parliamentary Medical Committee heard an address, on March 28th, from Sir GEORGE BUCHANAN on the health work organized by the League of Nations. He said this was mixed with questions of international health, which were dealt with by other machinery and might be divided into intergovernmental health work and "fraternity" and mutual education. To the International Health Office at Paris were allocated formal agreements and conventions, general epidemiological discussions, and monthly bulletins, and the Consultative Council of the League of Nations Health Organization. To the Health Organization at Geneva were allocated combined expert studies, standards, disease work, intelligence services, special missions, and work referred to the Organization by the League Assembly or Secretariat. The League's health budget was for about £40,000 annually, plus a Rockefeller grant of £20,000. The British delegate was nominated by the Foreign Office to represent Great Britain, not merely the British Ministry of Health. He was elected as British member of the League's Health Committee, and also attended with the British delegation at meetings of the Assembly and Council, when desired, as British technical adviser. Sir George gave examples of the work done by the Paris and Geneva organizations in liaison on the International Sanitary Convention of 1926, and in regard to therapeutic and physiological standards. International standards had now been fixed for insulin, pituitary extract, digitalis, arsenobenzols, etc., serum, and vaccine standards for diphtheria, tetanus, and dysentery, and serum diagnosis test standards for the Wassermann, Sachs-Georgi, and other tests. Combined organization had been arranged against epidemics in Poland and Uganda, and was proposed against yellow fever in Africa. Special disease studies had been made both at Paris and Geneva into small-pox and vaccinia, malaria, cancer, Leishmaniasis, and other diseases, and had been of great value. The "fraternity" work, which had become more important each year, was essentially between public health departments, universities, medical societies, and individual experts, and had little official character. The Medical Committee heard Sir George Buchanan's remarks concerning small-pox with special interest. Subsequently the Committee considered a letter from the Hinchin Board of Guardians asking its support for a proposal that the Ministry of Health, in order to check the spread of small-pox by vagrants, should close all casual wards for three weeks or issue an order authorizing the detention of casuals for that period. The Committee decided to take no action. Dr. DRUMMOND SNIELS, the honorary secretary of the Committee, spoke on the proposed visit to be paid by medical members of Parliament to military hospitals and medical institutions at Aldershot. Regarding the Edinburgh Corporation's bill asking further powers to control venereal disease cases the Committee agreed that while it could take no official attitude towards the proposals its members ought to endeavour to ventilate the subject by speaking for or against as medical men when the bill was discussed in the House of Commons at a date not then fixed.

The Royal assent was given on March 28th to the Protection of Lapwings Act, the Industrial and Provident Societies

(Amendment) Act, the British Guiana Act, and the Rating (Scotland) Amendment Act.

Mr. Hayes, on March 28th, introduced a bill to amend the Firearms Act, 1920, in respect to the definition of firearms. He explained that he proposed to include within the definition of firearms "toy" pistols which had the barrel and chamber plugged, but which were capable, by boring, of conversion into lethal weapons. The bill was read a first time.

### Tetra-ethyl Lead in Motor Spirit.

#### Committee of Inquiry Appointed.

In the House of Lords, on March 29th, Lord BUCKMASTER asked the Government the constitution of the committee set up to inquire into the danger arising from the use of tetra-ethyl lead in motor spirit; why the committee was not sitting in public, and when their report was expected. He moved that serious warning should be at once issued by the Ministry of Health on the possible danger from the use of tetra-ethyl. Lord Buckmaster said that the committee had been set up in pursuance of a resolution which was before the Lords about a month earlier. Ethyl spirit, he said, had been advertised in this country for more than nine months, but no warning had been issued to any person who was compelled by his occupation to use it. Employees at petrol stations had heard nothing of the danger from the use of this spirit, and one had told him that it was splashing over his hands daily. Since last speaking in the House on the subject Lord Buckmaster had received a letter from a medical man who said he had examined parts of a car which had run for some 3,000 miles on ethyl petrol. The deposits proved to contain over 50 per cent. of soluble lead. Mr. J. L. Jeffery of the Board of Trade had examined the parts and confirmed the chemical findings. On December 22nd this doctor had handed all the facts in writing to the Board of Trade, but nothing further had been done. The same doctor, writing in the medical press, had asserted that in the United States, between the autumn of 1923 and the spring of 1925, the fatal cases numbered from 11 to 16, and about 100 non-fatal cases were known to have occurred. Death from this poison was preceded by one of the most hideous forms of insanity, much resembling delirium tremens. The poison was almost incapable of remedy, was cumulative, and was slow in action. Lord Buckmaster said he had a letter asserting that Dr. Harris, the Commissioner for the Board of Health for New York City, had forbidden the sale of this spirit there, though it was still allowed in New York State. Switzerland had forbidden its sale throughout the whole country. Lord GAGE, replying for the Government, at once read the names of the committee which had been set up. They were as follows:

*Chairman:* Sir Frederick Willis, K.B.E., C.B., who was until recently Chairman of the Board of Control.

*Departmental Representatives:*—Ministry of Health: Sir George Buchanan, C.B., M.D. Home Office: Dr. J. C. Bridge, F.R.C.S. (Senior Medical Inspector of Factories). Air Ministry: Mr. D. R. Pyc, M.A. (Deputy Director of Scientific Research). Medical Research Council: Sir Charles J. Martin, C.M.G., D.Sc., F.R.S., F.R.C.P. (Director of the Lister Institute). Government Chemist: Sir Robert Robertson, K.B.E., D.Sc., F.R.S. War Office: Major W. R. Galloway, O.B.E., M.C., M.B. (Director of Experiments in the Chemical Warfare Department). Department of Scientific and Industrial Research: Dr. C. H. Lander, D.Sc. (Director of Fuel Research).

*Non-official Members:*—Mr. A. Chaston Chapman, F.R.S., F.I.C., Sir William Willcox, K.C.I.E., C.B., M.D., F.R.C.P., Professor W. E. Dixon, M.D., F.R.S.

*Secretary:* Mr. S. F. S. Hearder, Ministry of Health, Whitehall, S.W.1.

Lord Gage said the committee would have to examine conditions throughout the country to see what precautions were taken by manufacturers and distributors, how far the action of the trade in informing the public sufficed, and how far it should be reinforced by statutory regulations. Laboratory research might be needed, with repetition of some of the American experiments. The investigations of the committee must be prolonged. Meanwhile the Government could not, by an official warning, prejudice the products of a particular firm without the strongest reason for doing so. There had been three inquiries into tetra-ethyl in the United States. The last, a very elaborate one, by the Surgeon-General's Department in Washington, involved experiments not only on animals, but on human beings. These committees had not found actual evidence that harm had resulted from the ordinary commercial use of tetra-ethyl petrol. Though no legislation was introduced the committees did recommend precautions both in manufacture and in distribution in garages. Writing on March 3rd to the Ministry of Health the Surgeon-General said:

"As a result of this report, the precautions recommended by this Commission (that is, the American Commission) for the manufacture of the substance have been carried out, and the effect of the use of ethyl spirit on the distributors throughout a large area of this country has been under the immediate observation of the Public Health Service in co-operation with the authorities of the

University of Cincinnati and others. I may add that, notwithstanding the late publicity given to the investigations and the general use of the substance all over the United States and Canada, no instance of lead poisoning has been reported in the lay or medical press or to any of our Federal or State authorities."

Lord GAGE asserted that during the five years the spirit had been in use in America no one had discovered a single case of lead poisoning from its use, though its consumption ran into millions of gallons a year. Tetra-ethyl was blended in this country under precisely similar conditions to those prevailing in America, and the Home Office had satisfied itself that the precautions were adequate to meet the risk of poisoning. If the new British committee found evidence controverting the findings of the American committees it could issue an interim report and the Minister could immediately apply to Parliament for powers. A Petroleum Bill awaited third reading in the House of Commons, and contained a clause enabling the Minister to make regulations for the distribution or manufacture of any class of petroleum spirit which appeared to him dangerous or injurious to health. Other substances containing lead compounds equally poisonous were manufactured and retailed subject only to the same restrictions and regulations as prevailed in the manufacture and distribution of this ethyl petrol. The Minister of Health saw no use in prejudicing the inquiry by condemning this substance before the committee had reported, and he was not persuaded that the public would suffer serious risk before the committee issued an interim report.

Lord HALDANE suggested that the Government should instruct the committee to issue an interim report on the question whether *prima facie* this substance was of a dangerous character and whether there ought to be some restriction in its use.

Lord MONTAGU OF BEAULIEU said that so far as his experience of tetra-ethyl was concerned there had been no definite bad results. There was danger if tetra-ethyl was allowed to rest on the hand and danger from the exhaust. The ordinary exhaust from a motor car consisted of carbon monoxide. If they added tetra-ethyl lead it made carbon monoxide more liable to cause insensibility. He had definite cases of the effects from the exhaust of a car running on the road, in one case upon both the driver and the occupants of the saloon that was being driven. The inquiries in the United States were not very conclusive, when read carefully, and, in addition, the sale of tetra-ethyl was not allowed in New York City. It was absolutely barred in the tunnel which ran under the Hudson river, because of its effects. There was sufficient evidence to make people who used this petrol very careful in doing so. The Government, he considered, had been somewhat dilatory in setting up an inquiry.

Lord SALISBURY said the committee which had been appointed was going to sit at once, and had been asked to expedite its findings. He did not see what more could be done. Undoubtedly the American inquiry was very careful. By raising a debate twice Lord Buckmaster had let those interested throughout the land know that questions had been raised in Parliament about the poisonous qualities of tetra-ethyl. He would see that the suggestion of a request for an interim report was considered.

Lord BUCKMASTER renewed his suggestion that the Government should issue a warning to the public. Lord SALISBURY cited a warning issued by the firm selling ethyl petrol. Lord BUCKMASTER said that that warning, so far as he knew, was not read by the people who handled the spirit. Nobody denied the spirit was dangerous. Lord Buckmaster's motion calling upon the Government to issue a warning was then defeated by 36 to 21.

The terms of reference to the committee, which was announced in the House of Lords on Thursday, March 29th, are: "To inquire into the possible dangers to health resulting from the use of motor spirit containing lead tetra-ethyl or similar lead-containing compounds, and to report what precautions, if any, are desirable for the protection of the public or of individuals in connexion with the use or handling of such motor spirit."

#### Small-pox.

Mr. CHAMBERLAIN told Mr. J. Baker, on March 28th, that he had renewed the instruction that, with a view to detecting cases of small-pox, all persons admitted to the casual wards of Poor Law institutions should be medically examined. Small-pox was known to the Ministry of Health to have occurred in some sixty casual wards during the present year.

Answering Dr. Fremantle on March 29th, Mr. CHAMBERLAIN said the Metropolitan Asylums Board, the Surrey Small-pox Hospital Committee, the Uxbridge Joint Hospital Board, and the Willesden Urban District Council had respectively available for small-pox 2,123 beds, 19 beds, 26 beds, and 25 beds; of these, only 6 were then occupied. Dr. FREMANTLE asked whether Mr. Chamberlain knew that two cases of small-pox in the infirm ward at the Brentford Union institution had to be isolated there from March 16th to 22nd, and another case from March 25th. Mr. CHAMBERLAIN said he knew of this. Dr. FREMANTLE asked whether the Minister would secure that vacant beds in small-pox hospitals were available for cases of small-pox from neighbouring areas subject

to proper chargeability of expenses. Mr. CHAMBERLAIN replied that he had no power to require authorities possessing small-pox hospital accommodation to admit patients from other districts, the councils of which had made no provision or inadequate provision for the purpose. Dr. FREMANTLE asked whether Mr. Chamberlain was using his powers of persuasion to get this selfish policy of local authorities altered. Mr. CHAMBERLAIN said he could not accept that definition. In most infirmaries provision was made for isolation treatment of infectious cases.

On March 29th Mr. GROVES asked whether butchers buying calves at the Government's Hendon lymph establishment were informed that they had been used for inoculation, whether butchers offering such calves for sale were compelled to exhibit a notice that the calves had been used for inoculation; for what purpose rabbits were inoculated at the Hendon establishment, and whether rabbits so used were destroyed. Mr. CHAMBERLAIN said Mr. Groves had already had facilities for visiting the Hendon establishment, and suggested that he should go there again to secure information. Two Government clerks had been occupied for a whole day answering Mr. Groves's last question, and for him to ask for further detailed information was scarcely reasonable. Mr. MONTAGUE pressed for a reply to the question about butchers and calves. Mr. CHAMBERLAIN said butchers were not informed that calves had been used for inoculation, nor was there any compulsion to exhibit a notice of the fact. Answering a further question by Mr. Groves, Mr. CHAMBERLAIN said that after production of the lymph a calf was not used again, but was slaughtered. The carcass was at the disposal of the contractors who supplied it, and was sold for food.

#### Shops Bill.

When a Standing Committee of the House of Commons considered the Shops Bill on March 27th Miss WILKINSON moved to omit the subsection permitting a shopkeeper to supply goods after hours if reasonable grounds existed for believing that the article was required in the case of illness. She said that articles sold in chemists' shops and other things required as matters of life and death were already covered by other clauses of the bill. Spirits were dealt with by entirely different legislation, and the subsection she was discussing would apply very largely to the contents of the average grocer's shop, none of which was likely to be needed in cases of sudden illness. She instanced beef-tea, mustard, and oil. Dr. VERNON DAVIES denied that the other subsection to which Miss Wilkinson referred provided for all the goods which were needed in sudden illness. Sir WILLIAM JOYNSON-HICKS undertook to see the bill made clear that if the shop was open for the needs of sickness it was not to be used for the sale of other goods. The amendment was withdrawn and the clause added to the bill.

**Death after Operation for Adenoids.**—On March 22nd Mr. MACQUEEN asked Lord EUSTACE PERCY whether he would inquire into the circumstances of the death of a boy at Oulton, Wigton, Cumberland, who was a healthy child in Oulton School until he underwent an operation for tonsils and adenoids. Mr. Macquisten was operated on for tonsils and adenoids. Mr. Macquisten alleged this had been done in spite of protests by the boy's mother, and asked under what authority the action had been taken. Lord EUSTACE PERCY said he had received a report on this case from the school medical officer. He understood that the concurrence of the boy's mother was obtained before the operation was performed. The boy was operated upon at a hospital by a specialist; he was kept in the hospital for two nights after the operation, and was apparently quite well when discharged. Death was due to complications which subsequently arose, and this regrettable occurrence was not due to defect or failure in the authority's arrangements for treatment.

**Housing Statistics.**—On March 26th Mr. CHAMBERLAIN, in reply to General Clifton Brown, said that the numbers of houses completed by rural district councils in England and Wales up to March 1st, 1928, were 92,532 under the Housing Act, 1923, and 24,525 under the Housing Act, 1924. The number of houses not exceeding £26 rateable value erected in rural districts without subsidy during the period from April 1st, 1923, to September 30th, 1927, the latest date for which figures were available, was 76,357.

**National Insurance: Ophthalmic Benefit.**—Mr. CHAMBERLAIN, replying on April 2nd to Lieut.-Colonel Mason, said that there was not in the National Health Insurance Bill, nor was there any intention to include in any regulations that might be made under it, any provision which would place an insured person in a less favourable position than hitherto with regard to arrangements for obtaining ophthalmic benefit.

**Pensions.**—Mr. ROBINSON asked Major Tryon, on March 29th, how many pensioners suffering from tuberculosis had been put on treatment allowances during the three months ended February 29th. Major TRYON said 2,459 cases terminated a course of treatment with allowances, and 1,221 fresh cases were admitted to such treatment. It was not the policy of the Ministry of Pensions only to pay treatment allowances if a man was in an institution.

#### Notes in Brief.

Sir KINGSLEY WOOD said, on March 21st, that Mr. Chamberlain was taking steps to set up a committee to inquire into the training and supply of midwives.

In its report, which will be issued shortly, the Voluntary Hospitals Commission will deal with the financial difficulties resulting from the fact that many of these hospitals have to treat cases caused by motor accidents.

The Minister of Health has no power to order a notice to be displayed in all shops where synthetic cream is sold.

## Medical News.

THE KING visited the Woolwich War Memorial Hospital on March 27th, when he was received by Mr. E. Kemp, L.C.C., the chairman of the hospital; Lord Dawson, consulting physician; Sir Berkeley Moynihan, consulting surgeon; and Mr. Cecil Rowntree, chairman of the Medical Committee. His Majesty made a tour of the wards and special departments, and inspected the new stainless steel and chromium-plated furniture in the operating theatres, made by Messrs. Arnolds to Mr. Rowntree's designs. His Majesty expressed his satisfaction at hearing that all the equipment was of British manufacture, and congratulated the chairman on the beauty and efficiency of the hospital. Before leaving the King planted a cedar tree in the grounds.

To celebrate the centenary of the Royal Free Hospital, and in aid of the centenary appeal for the new extensions, the medical staff and students, with some other friends of the hospital, are organizing a ball to take place on May 1st, from 9.30 p.m. to 2 a.m., at the British Medical Association House, Tavistock Square. There will be dancing in the Great Hall to Newman's Band, with short cabaret turns by well-known artists at intervals, while ample space for bridge players will be provided in the Hastings Hall. Tickets, to include supper, are one guinea each, and may be had from any member of the committee, from the Royal Free Hospital, and from the Honorary Secretary, May Day Ball, 24, Mecklenburgh Square, W.C.1.

A MEETING of the West Kent Medico-Chirurgical Society will be held on Friday, April 13th, at 8.45 p.m., at the Miller General Hospital, Greenhithe, S.E.10, when Mr. R. Ogier Ward will give an address on some difficulties in the diagnosis and treatment of urinary diseases.

UNDER the auspices of the Fellowship of Medicine a special course in infants' diseases for medical officers of welfare centres and others will be held at the Infants Hospital, Westminster, from May 7th to 19th. In addition to lectures and demonstrations visits will be paid to the Model Pasteurizing Plant, Willesden; the Nursery Training School, Hampstead; the V.D. Centre, Tavies Inn; the Home for Blind Babies, Chorley Wood; and the Infants Hospital Convalescent Home, Burnham Beeches. Details may be obtained from the secretary of the Fellowship, 1, Wimpole Street, W.1. Similar courses at the Infants Hospital will be held in August and December.

A POST-GRADUATE course on diseases of the nervous system will be held at the National Hospital, Queen Square, from May 7th to June 29th, consisting of clinical lectures and demonstrations each week-day afternoon, except Wednesday and Saturday, work in the out-patient department each week-day, except Saturday, and a series of seven pathological lectures and demonstrations. A course of eight lectures on the anatomy and physiology of the nervous system will be arranged if there are sufficient applicants. There will also be a course of twelve clinical demonstrations on Tuesday and Friday afternoons, chiefly on methods of examination of the nervous system. A limited number of students can be enrolled as ward clerks. Full details regarding the course and these appointments may be obtained from the secretary, Medical School, National Hospital, Queen Square, W.C.1.

THE seventh International Congress of Photography, which is to be held in London from July 9th to 14th, under the auspices of the Royal Photographic Society, is the first to take place in this country. All branches of photography and its applications, including radiography, photomicrography, and methods employed in chemistry and biology, will be discussed in the various sections and illustrated in a series of exhibitions during the congress. Offers of radiographic prints, photomicrographs, and photographs of biological interest should be sent as soon as possible to the honorary secretary to the Organizing Committee, the Science Museum, South Kensington, S.W.7.

THE Council of the Royal Society of Arts announces that the next award of the Swiney Prize, which on this occasion will be for the best published work on medical jurisprudence, will be made in January, 1929. Dr. Swiney, the donor of the prize fund, who died in 1844, left £5,000 to the society to provide, on every fifth anniversary of his death, a prize consisting of a cup, value £100, and money to the same amount, the awards being made alternately for medical and general jurisprudence. Any person desiring to submit a work or to commend a work for consideration should do so in writing to the secretary of the society, John Street, Adelphi, W.C.2, not later than November 30th; the award is made jointly by the Society of Arts and the Royal College of Physicians. The last two awards for works on medical jurisprudence, in 1909 and 1919, were made to Dr. Charles

Mercier for his books, *Criminal Responsibility* and *Crime and Criminals* respectively. One of the earliest prize-winners, in 1859, was Dr. Alfred Swayne Taylor, whose *Medical Jurisprudence* has lately appeared in its eighth edition, more recent awards going to Dr. C. M. Tidy in 1889 and Dr. J. Dixon Mann in 1899.

AS announced in our advertisement pages applications for the Dickinson Travelling Research Scholarship in Medicine and the Dickinson Surgery Scholarship must be made by May 1st to Mr. Frank G. Hazell, secretary to the Trustees, Manchester Royal Infirmary, from whom further information can be obtained. The former is of the value of £300, tenable for one year, and candidates must have graduated at the University of Manchester, with distinction in medicine and surgery, in any of their academic years immediately preceding the award of such scholarship. The surgery scholarship is open to students who shall have received at the University of Manchester and the Royal Infirmary instruction in pathology, medicine, and surgery necessary for obtaining the degrees of M.B., Ch.B. Manch.

THE Royal Westminster Ophthalmic Hospital will move to the new building in Broad Street, High Holborn, W.C.2, on April 10th.

THE *British Guiana Medical Annual* for 1925 has been recently issued at the cost of 7s. It contains the transactions of the British Guiana Branch of the British Medical Association for the years 1922-24, four original articles, and two clinical notes. A supplement deals with leprosy in British Guiana, including the related statistics and legislation, and also a note on treatment. The public health and medical statistics of the colony, usually published in this Annual, have been postponed to the 1926 issue, which is in course of preparation.

THE February issue of the *Kenya and East African Medical Journal* contains an account of the annual meeting of the Kenya Branch of the British Medical Association, and a review of the medical history of the colony during 1927. Attention is drawn to the improvement of railway communications, and to the closer co-operation of the public medical and health services in the various territories in East Africa under British rule. Other articles in this issue deal with the serological diagnosis of *B. pestis*, the treatment of ulcers with Stockholm tar, and inoculation of the monkey as a means of diagnosis of small-pox. The series of simple notes on tropical diseases is continued, with a practical account of the treatment of plague.

THE third congress of the International Society for Logopaedics and Phoniatrics will be held at Vienna from July 12th to 14th. Further information can be obtained from Professor E. Fröschels, Ferstelgasse 6, Wien IX.

THE eighth International Congress of Dermatology and Syphilology will be held at Copenhagen from August 5th to 8th, 1930. Further information may be obtained from the general secretary, Dr. S. Lomholt, Raadhnsplads 45, Copenhagen.

A COURSE in oto-rhino-laryngology will be held at Strasbourg, under the direction of Professor Georges Cannyt, from July 2nd to 14th.

THE *Journal of the Egyptian Medical Association* has during the last ten years been printed solely in the Arabic language. Commencing with the issue of January, 1928, translations, or summaries, of the articles appear in English, French, German, or Italian. The first number published under the new conditions includes articles in English on the biochemical race-index of the Egyptians; hilariazis of the conjunctiva, illustrated by coloured plates; and the determination of the solubility of digitoxin.

THE *Bruxelles-Médical* has recently published a special issue devoted to the annual congress known as the Journées Médicales de Bruxelles, held last June. The issue contains abstracts of the principal communications, with portraits of their authors, and an illustrated account of the social functions.

A NATIONAL fund is being created in Sweden for presentation to King Gustaf V as a gift on his seventieth birthday in June this year. The King intends to expend the fund in promoting cancer research. A special Institute may be established in Stockholm.

THE following appointments have recently been made in foreign faculties of medicine: Dr. Hermann Straub of Greifswald, professor of internal medicine at Greifswald; Dr. A. Kohlrausch of Greifswald, professor of physiology at Tübingen in succession to the late Professor Trendelenburg; and Dr. Belak, professor of public health at Debrecein.

CHAIRS of therapeutic hydrology and climatology have been founded at the faculties of medicine of Paris, Lyons, and Montpellier, with Drs. Villaret, Pléry, and Girard respectively as their first occupants.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

**ORIGINAL ARTICLES** and **LETTERS** forwarded for publication are understood to be offered to the **British Medical Journal** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **British Medical Journal** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **British Medical Journal** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the **British Medical Journal**, *Aitology Westcent, London.*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Articulate Westcent, London.*

**MEDICAL SECRETARY**, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshagh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

### QUERIES AND ANSWERS.

#### CHRONIC BRONCHITIS AFTER GAS POISONING.

"D. M. M." asks for any suggestions in treating an obstinate case of bronchitis caused originally by gas poisoning in France. The secretion is both abundant and free. All the remedies indicated in chronic bronchitis, including tar, mineral acids, and belladonna, have been of no avail. The patient is aged 54 and otherwise healthy.

#### NEPHROSTOMY.

A CORRESPONDENT inquires as to the use of the word "nephrostomy" in Mr. J. F. Dobson's article on "The late results of operation for renal calculus," published in our issue of March 24th (p. 486).

\* \* \* We have referred the point to Mr. Dobson, who writes: "Nephrostomy" implies incision and drainage of the kidney, and is the term which ought to be used in preference to "nephrotomy," which merely means an incision into the kidney and does not imply drainage. The term "nephro-lithotomy" is used to describe the operation of incision of the kidney, extraction of the calculus, and suture of the kidney. If a surgeon incised the kidney with the intention of removing a calculus, could not find the calculus, and closed the incision by suture, that operation would be correctly described as a "nephrotomy." With our more precise methods of diagnosis the operation of exploratory nephrotomy is now rarely performed; but many surgeons will remember the period when such operations were rather common. When nothing was found the case was labelled "nephralgia," and confident assertions were made by the more optimistic operators that the patients were cured of their symptoms by the interference.

#### INCOME TAX.

##### Motor Car Allowance.

"W. G. S." bought a car in January, 1923, for £475 and sold it in 1927 for £60, when he bought a car of another make for £265. He has been allowed a total sum of £132 in respect of depreciation on the old car for the three years to 1927-28 inclusive.

\* \* \* The allowances to be claimed are: (1) Obsolescence allowance—as an expense of the year 1927—the actual sum expended, namely, £265—£60=£205. (Note.—This does not exceed the cost of the car replaced after deducting the total wear and tear allowances given thereon and the sum obtained for the old car.) (2) Depreciation allowance for 1923-29, £265 at 15 per cent.=£40.

#### Appointments and Post-Graduate Study.

"F. C. B. G." is in practice in the provinces as an ophthalmic surgeon, and holds an appointment as clinical assistant at a London hospital. Can he deduct as a professional expense (1) the expense of travelling to the hospital; (2) the cost of attending classes for further study; and (3) the expense of attending meetings of the Royal Society of Medicine, including the incidental hotel expenses?

\* \* \* (1) We understand that the authorities do not object to the inclusion of the fees in the general return and the deduction

of the travelling expenses, but this presumably proceeds on the assumption that the appointment is one of appreciable value—for example, we imagine they would object to the deduction of expenses to an amount in excess of the gross value of the appointment. From the point of view of strict law, and apart from any departmental concession, the deduction is not due. (2) and (3) There is neither law nor concession to support the claim.

### LETTERS, NOTES, ETC.

#### MATERNAL MORTALITY AND PELVIC DEFORMITY.

DR. KATHLEEN O. VAUGHAN (London, W.2) writes to suggest that a factor which has been overlooked in discussing the causes of maternal mortality is maldevelopment of the female pelvis. No ante-natal care during pregnancy can remove a defect produced during growth of the pelvis, and therefore, she says, considerably more attention should be devoted to this part of the body in early life. The complex nature of the processes involved is indicated by the fact that sexual differences are present in the pelvis by the fourth month of intrauterine life, that twenty-one centres of ossification are concerned in the developing sacrum, twelve more in each innominate bone, and forty-five centres continue to grow actively until the age of 25, when the process is complete. Thus any failure in the factors necessary to proper development and ossification may have very serious consequences in later life. The head only doubles in size from birth to maturity, whereas the size of the pelvis at puberty is thrice that at birth, but the three bones composing the innominate are still only united by cartilage at the acetabulum. Dr. Vaughan suggests that the greater elasticity of the pelvis at puberty may explain the partiality for early marriage in the East, in view of the assistance given to childbirth by pelvic elasticity. She emphasizes the necessity for further investigation of the growth of the pelvis, particularly during the rapid stage from 8 to 15, and calls attention to the possibility of defective light and ventilation in houses and workshops giving rise to imperfect pelvic development in girls.

#### APPENDICECTOMY DURING HERNIOTOMY IN AN INFANT.

MR. H. C. CRAVEN VEITCH (Huntingdon) refers to Dr. D. Mac-kouzie's case (March 17th, p. 443) and writes: On March 22nd, 1927, a male infant, 7 weeks old, was admitted to Huntingdon County Hospital under my care with a strangulated right inguinal hernia. A general anaesthetic was given, and when I opened the sac I found the caecum nipped in its neck and the appendix lying free in the sac. I removed it, completed the operation in the usual way, and circumcised the baby. I believe that the appendix in a hernial sac is not a very rare find; I have seen it previously myself. I have, however, never seen another in a strangulated hernia or noticed one reported. This is the youngest age at which I have removed an appendix or encountered a strangulated hernia.

#### LIME-DEFICIENT FOOD AND CARDITIS.

DR. G. ARBOUR STEPHENS (Swansea) writes: While on a recent holiday to the West Indies I was agreeably surprised to find that there were no cases of heart disease or any deaf and dumb children on the islands. The children feed mainly on vegetables, fruit, and ground provisions—all grown on soil well impregnated with lime from the coral—together with milk from goats or cows with lime from the condensed variety. I am inclined to ask to what extent or the condensed variety. I am inclined to ask to what extent this substantiates my theory that acute rheumatism and carditis occur only in that type of child whose food has been markedly deficient in lime, combined with a perverted appetite for acids, such as vinegar. My attention has been drawn to the interesting report by Dr. Orr (January 28th, p. 140), together with your comments thereon, and I wish to point out that whilst rate of growth is important, the direction of that growth is also very important. Cancer cells grow quickly, but in the wrong direction, and consequently it is all important that growth in childhood should be towards the development of that type of child which should be towards heart disease—namely, the milk-fed one never falls a prey to heart disease—namely, the milk-fed one never falls a prey to heart disease. The curative value of calcium with no craving for vinegar. The curative value of calcium salts in acute ulcers, such as chilblains, of calcium iodide in chronic ulcers, of calcium permanganate in gastric ulcers, and of calcium in the colloidal form in cardiac ulcers, serves to suggest that these salts satisfy a physiological need.

#### ERRATUM.

DR. H. M. HANSCHALL has called attention to an obvious slip in his paper on the injection treatment of varicose veins, published in the *Journal* of March 31st. In page 543, line 21 published in the foot of column 1, the word "methane" should, of course, be "urethane."

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 47, 48, 49, 52, and 53 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 50 and 51.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 120.

## A Lecture

or

## THE INTENSIVE ALKALINE TREATMENT OF GASTRIC AND DUODENAL ULCER.

DELIVERED TO THE KENT BRANCH OF THE BRITISH MEDICAL ASSOCIATION

BY

HUGH MACLEAN, M.D., D.Sc., F.R.C.P.,

PROFESSOR OF MEDICINE, UNIVERSITY OF LONDON; DIRECTOR OF THE CLINICAL MEDICAL UNIT, ST. THOMAS'S HOSPITAL.

To the general practitioner the treatment of gastric and duodenal ulceration has always bristled with difficulties. Patients suffering from these lesions are frequently encountered in general medical practice, and very often the results of medical treatment are unsatisfactory. If relief does not come within a short time the patient is generally handed over to the surgeon, since it is considered that, on the whole, medical treatment in these cases is not very efficacious. Surgical intervention is not infrequently productive of excellent results; on the other hand, the last state of the patient may be worse than the first, and though surgery has many successes to its credit in this field it has also many failures. Different views are held as to the exact indications for surgical treatment, but the appearance of a well-marked niche or so-called "penetrating" ulcer in the radiogram is often accepted as evidence that the condition is not likely to be benefited by medical treatment, and so operation follows. In many cases operation is quite unnecessary, for excellent results may usually be obtained by simple medical means which can be quite easily carried out by any medical practitioner with little or no inconvenience to the patient. This can be done by the use of intensive alkaline treatment. Before describing this treatment in detail it is necessary to make a few preliminary observations.

## THE USE OF ALKALIS IN STOMACH LESIONS.

For a very long time indeed alkalis have been used by almost every medical practitioner in the treatment of gastric conditions. That these substances have a very marked action in relieving distressing gastric symptoms is known to all. How they produce this effect is a matter for discussion, and opinion on this point is not unanimous. According to some observers this action is an indirect one, while others take the view that it is due to the antacid properties of these bodies. Personally, I have little doubt that the latter view is the correct one. If the action were an indirect one after absorption it is impossible to imagine that relief from symptoms would follow so quickly after ingestion as is usually the case.

Although almost every medical man has recognized the value of alkalis for many years it is somewhat strange that this fact has not resulted in a more intensive use of alkali treatment. Though undoubted benefit was derived from small doses of these bodies it was recognized that this benefit was usually but a temporary one, and that very often symptoms recurred after a short time. Assuming that alkali produces these good effects by neutralizing the hydrochloric acid of the gastric juice, it is a matter for wonder that more physicians did not push the treatment to its ultimate conclusion and give sufficient alkali, not only to neutralize the acid temporarily, but to do so for long periods. Logically, this would be the most likely means to cure an ulcer, and I will try to convince you that this statement is correct. It is quite true that several medical men did give large doses of alkali, but to Sippy<sup>1</sup> belongs the credit of first pointing out that an ulcer could usually be cured by giving sufficient alkali to keep the stomach alkaline for several days or weeks. Though Hurst,<sup>2</sup> in a very interesting paper, published an account of Sippy's method, it does not appear to have been taken up with any enthusiasm in this country. Perhaps this was due to the fact that Sippy's directions were somewhat elaborate. In spite of certain alarming statements as to the danger of the treatment it is, in ordinary circumstances, perfectly safe. For five years my colleagues and I have used a

simple modification of the method with most excellent results. Altogether over 350 patients have been treated without any untoward symptoms. Indeed, I have not been able to find a single case of any toxic effects when our modification was carried out. The method is now in use by many of the staff of St. Thomas's Hospital and by many of our recent graduates, yet I have found no one who has had the slightest difficulty with the treatment. In our experience there is no method that gives such excellent results in a short time. It is simple, requires no special knowledge or supervision, and can be carried out at the patient's home, however humble his circumstances.

## EXPERIENCES WITH INTENSIVE ALKALINE TREATMENT.

Personally, I have always been interested in the physiology and pathology of gastric secretion, and very many years ago had frequently given large doses of sodium bicarbonate and other "alkalis" in cases of severe dyspepsia. In 1920, when I was put in charge of beds at St. Thomas's Hospital, we began to test various methods of treatment for gastro-duodenal ulceration, and among these methods was the use of large doses of alkali. This continued until 1923, when it appeared to us that the results with alkali were very much better than those afforded by other means. In 1923 the majority of our gastric cases were treated by the intensive alkali method, with such excellent results that since 1924 the method has been used as a routine one. The results have been gratifying in the extreme, and far better than we had hoped for. Uncomplicated ulcers clear up in a short time, as indicated by x rays, and in the great majority of cases all the symptoms disappear quickly. Often large "penetrating" ulcers clear up in a few weeks. So far we have not had a single instance of an ulcer recurring at the site at which it was formerly present as indicated by radiograms. Our operation list has gradually diminished, and for the last year not a single case out of over 70 treated has required operation. Even in patients suffering from pyloric stenosis an operation can often be avoided by the use of alkali treatment. For the last year we have had only one patient readmitted to the wards after he had undergone treatment. These results are altogether better than any we have had by other means, and seem to us to indicate that in the judicious use of alkali we have a method that will cure the average case of uncomplicated duodenal or gastric ulcer.

In my monograph<sup>3</sup> on gastric diseases published in 1925 I pointed out the great value of this method of treatment, and further experience has more and more impressed me with its value. At the beginning of this year my colleagues and I published a paper showing a number of radiograms illustrating the excellent effects obtained by this treatment.<sup>4</sup> This article elicited a certain amount of criticism which had to a large extent but little bearing on the facts, but nothing helpful transpired. Apparently, however, if we may judge from the mass of correspondence received from medical practitioners, this article has served to stimulate interest in the method. For some years I have described the alkaline treatment at various meetings of medical men, and invariably, so far as I know, those who have tried it have had good results. We hope to publish a detailed account of our medical unit results at an early date, but, so far, the conclusion we have arrived at is to the effect that the method will cure the ordinary case of gastro-duodenal ulceration. Patients with adhesions and other complications are probably not suitable cases, but we have some evidence which may suggest that even cases with adhesions to sundry organs may do quite well. On this point, however, we are not certain at present. We have so few failures that on general averages some of our successes probably had complications.

## THE RATIONALE OF INTENSIVE ALKALINE TREATMENT.

In nearly every case of severe dyspepsia and ulceration hydrochloric acid is present in the stomach secretion. Now it is well known that hydrochloric acid is very injurious in the case of an ulcer: it causes irritation and prevents healing. This has been amply proved by Bolton<sup>5</sup> and many others. To what extent the gastric peptin is also responsible for this deleterious action is unknown, but

this is of no great importance, since pepsin is inactive in the absence of acid. The hydrochloric acid is therefore the important factor in preventing the healing of an ulcer. While this is generally admitted, there seems to be a good deal of confusion regarding the matter. It is sometimes said that there is not necessarily any excess of acid concentration in gastro-duodenal ulceration. This is often true, but why worry about excess of acid? The ordinary normal acid secretion is sufficient to cause the damage. Very often there is a "hyperacidity" in the sense that the stomach continues to secrete acid after digestion is completed and the food has passed on to the intestine. This acid must do a very great deal of harm.

A theoretical objection to the use of large amounts of alkali is to the effect that it prevents gastric digestion. This is, however, exactly what we wish to prevent. If the food is passed into the stomach in a finely divided pulvaceous mass there is no need for gastric digestion. The food is passed into the duodenum and digested by the pancreatic juices lower down. Stomach digestion is not essential to health, and its temporary suspension will do no harm. Now it is a strange fact that ulceration practically never occurs in the alkaline small intestine. In the first part of the duodenum ulceration is common, and here acid frequently comes into contact with the mucous membrane; in the remaining parts of the duodenum, where an alkaline medium is the rule, ulceration is almost unknown. All this seems to indicate, on theoretical grounds, that ulceration is in some way associated with the presence of hydrochloric acid. This conclusion is enormously strengthened by the observation that ulcers will heal when they are no longer subjected to the action of acid, but are bathed in an alkaline medium.

#### DETAILS OF INTENSIVE ALKALINE TREATMENT.

Sufficient "alkali" must be given to prevent the presence of free hydrochloric acid in the stomach for some time. The substances generally used to neutralize the acid are sodium bicarbonate, magnesium carbonate or oxide, and calcium carbonate. In America magnesium-ammonia phosphate has been frequently used, and a mixture of calcium phosphate and magnesium phosphate has been recommended by Shattuck, Rohdenburg, and Booker.<sup>6</sup> Sodium bicarbonate being very soluble is an excellent antacid, but has the disadvantage that it tends to produce a secondary increased flow of acid. It is not satisfactory to use this substance alone, but when associated with less soluble bodies such as magnesium and calcium carbonate a very satisfactory mixture is obtained. It does not matter very much what combination of "alkalis" is used, but the following powder will be found to give excellent results.

Sodium bicarbonate	...	...	...	...	35s
Heavy magnesium carbonate	...	...	...	...	3j
Calcium carbonate	...	...	...	...	3i.
Bismuth oxy carbonate	...	...	...	...	3ii

It is important to have the bowels fairly free, and usually the above mixture, when given as directed, will produce a fairly free bowel movement. Should this be too free, some extra bismuth carbonate may be given, while, on the other hand, if constipation should prove troublesome extra "magnesia cream" may be given in doses sufficient to overcome the difficulty. Bismuth carbonate does not neutralize acid to any appreciable extent under ordinary conditions unless the acid is in greater concentration than is usually found in the stomach. It does, however, seem to possess some beneficial effect in gastric lesions, and is very useful in regulating any diarrhoea that may be present. Calcium carbonate is an excellent antacid with little effect on the bowels; magnesium carbonate, on the other hand, tends to act as a mild purgative, but is a good neutralizer of acid.

In order that the powder should have its maximum effect the patient should be put on liquid diet for a week or longer according to the severity of the condition and the intensity of the symptoms. Pain usually disappears within forty-eight hours, and the patient feels comfortable. If definite symptoms persist after two or three days' treatment it is probable that the condition is not an ulcer, or that adhesions to adjacent organs are present. The im-

portant point in treatment is to make certain that sufficient alkali is given to control gastric acidity. This is generally quite easily done during the daytime, but may be more difficult to accomplish during the night. It usually happens that the patient sleeps well if the acid is satisfactorily controlled, but if this is not the case he often wakes up complaining of pain and discomfort. It is therefore necessary to warn the patient that he must take a dose of the powder when he wakes up with feelings of discomfort. By this means the difficulty of preventing accumulation of acid during the night may be overcome.

Though it is best to have the patient in bed during the early stages of treatment, this is not always necessary, and we have treated many patients with success in the out-patient department. After some weeks of treatment the amount of powder given is gradually reduced. Patients with duodenal ulcer should, however, take the powder three times a day for two to three months. One most important point is to warn the patient that he must resume taking the powder and go on to liquid diet for a few days if any symptoms return. By this means an attack which might otherwise prove troublesome can be cut short. Patients who have had ulcers are sometimes liable to attacks of dyspepsia when they get run down, or after some infection such as influenza, but these attacks do not mean that there is a recurrence of the ulcer. This we have shown by x-ray investigation in such cases.

Though the exact details of treatment may be varied to suit different patients, the following general scheme will be found useful in the majority of cases.

#### First Week.

The patient is kept on a fluid diet consisting of milk, or milk with Benger's food. About three pints of milk per day are given in feeds of approximately 8 oz. every two hours. It is important, especially during the earlier part of the treatment, to prevent the clotting of milk in the stomach, and in order to ensure this 10 grains of sodium citrate are added to each feed of milk. This, of course, acts as a neutralizer of acid as well as an anti-coagulant. A small teaspoonful of the "alkali" mixture described is given every two hours shortly after the milk. The powder is best swallowed in a little water; care must be taken to stir the mixture thoroughly immediately before drinking. The powder is practically tasteless. About six to seven doses of powder are given per day. In addition, a double dose is given immediately before going to rest at night. The patient is warned that if he wakes up at night with any pain or discomfort he must take an extra dose of powder, or more than one dose if necessary.

Generally, it is quite easy to control the acidity by the above procedure, but in a few severe cases it is difficult. This failure to control the acidity usually becomes obvious to the patient by a return of the pain or discomfort. When this happens the patient must always take an extra powder; if the pain is due to insufficient neutralization it is immediately relieved by this extra dose.

In severe cases it is a good plan to give rather a smaller dose of the mixture every hour, for a two-hourly interval may allow of the passage of the whole of the powder from the stomach, with the result that free acid may be present. I have frequently used this plan with excellent results. In ordinary cases one or other of the above methods will generally give the desired effect. With patients suffering from renal disease or pyloric stenosis slight modifications may be advisable, but this will be discussed later.

#### Second Week.

If the patient has had no pain or discomfort for several days a little solid food is now added. If any discomfort or pain still persists the procedure of the first week is continued for a few days longer. If there are no symptoms the powder may now be reduced to five or six times a day; the quantity of milk being somewhat reduced also. Two or three eggs are now added to the milk and beaten up, or lightly boiled eggs are given. This is followed by small amounts of toast and butter, and cream. The diet is then gradually increased until by the end of the week the patient is taking, in addition to his milk,

a certain amount of toast, plain biscuits, butter, eggs, custards, a little porridge, and weak tea. A dose of powder immediately before retiring is taken as before, and the same care to take a powder during the night if pain occurs is still necessary; also an extra powder must be taken if pain or discomfort occurs during the day. Indeed, it is very important during all stages of the treatment that any discomfort arising by day or night should be immediately checked by a dose of powder.

#### Third Week.

Powder reduced to four or five times a day, and at bedtime. Food is gradually increased and should now consist largely of eggs, cream, toast, butter, plain biscuits, rice and other cereal puddings, porridge, custards, a little steamed white fish, and a small amount of potatoes. Sodium citrate need no longer be added to any milk taken.

#### Fourth, Fifth, and Sixth Weeks.

Milk is taken only in the usual average quantities. Powder is reduced to three or four times a day and at bedtime if no pain or discomfort is present. Food is still further increased with the addition of chicken, preferably creamed to begin with. In the fifth week a little meat (mutton or veal) may be taken, but only a small amount. By the end of this time the patient is taking a simple, nourishing diet, and the ulcer should be healed or well on its way towards healing. All the symptoms should have entirely disappeared in the average case.

#### After-Treatment.

The powder should be taken two or three times a day for another six to ten weeks. If there is an entire absence of symptoms the powder may then be given up during the day, but a dose should be taken at bedtime for several months. If any symptoms persist the powder should be taken two or three times a day for several months. A powder containing a suitable amount of magnesia may be taken at bedtime as a laxative for years without doing the slightest harm. It is impossible to give exact directions with regard to the length of time the powder should be taken, for this differs in different patients. It is, however, better to err on the safe side and to continue the powder for a long time if there is any evidence of dyspepsia.

It goes without saying that any source of infection, such as septic teeth or tonsils, should be attended to. Whether or not the wholesale extraction of teeth, so largely practised to-day, is an advantage or otherwise is a point for discussion.

#### Diet.

Much of what is written regarding diet is purely empirical and has no scientific basis in fact. Indeed, for many of the statements made in the literature there can be no foundation whatever. Rules regarding diet can be made quite simple, and may be summarized as follows.

1. The patient should avoid any article of food which would tend to cause physical irritation in the stomach. Now since raw vegetables are not digested to any appreciable extent in the stomach they should not be taken. Salads are therefore prohibited. The same applies to such articles as currants, raisins, nuts, or anything that would tend to leave an undigested residue in the stomach. If this principle is remembered the patient cannot go far wrong.
2. Meat, which tends to cause a marked secretion of gastric juice, should not be taken except in small amounts. Beef-tea and meat extracts of all kinds should be avoided.
3. Great care should be taken never to take too large a meal at one time, for this often tends to bring on symptoms.
4. The food should be thoroughly well masticated, so that it enters the stomach in a homogeneous pulpy mass.

#### Smoking and Alcohol.

Excessive smoking is a very frequent cause of gastric symptoms, and the less tobacco is indulged in the better. It should be given up entirely for a time. Alcohol should also be avoided, for it tends to excite the flow of gastric acid, which is so injurious to patients suffering from ulceration.

#### Other Considerations.

When the above treatment is carefully carried out as indicated, no other therapy is necessary in the average case. The tendency to excessive secretion of acid can sometimes be controlled to some extent by giving fats or oils. For this purpose they are of little value unless given on an empty stomach between meals, but if the patient can take olive oil, a dessertspoonful, two or three times a day, shortly before meals, may prove useful. Cream acts in a somewhat similar manner.

Various other measures may be used, but it is unnecessary to discuss them here. Probably belladonna is the most useful drug, but it is seldom necessary. The value of tonics and good general conditions as part of after-treatment is obvious.

#### RESULTS OF TREATMENT.

The rapidity and ease with which the majority of gastric ulcers heal when this treatment is used is very striking. It was hoped that actual photographs illustrating this point might be given in the present article, but this was impossible owing to printing difficulties. Drawings from four cases are therefore given. These have been carefully copied from the originals by an expert, and have been drawn to scale; they present exactly the same appearances as the original photographs, and show well how quickly these

FIG. 1.—Case 1. X-ray findings. (a) January 3rd; (b) January 19th; (c) January 27th.

ulcers disappear without leaving any trace whatever of their presence.

#### CASE 1.

A police sergeant, aged 38, who had had symptoms for over nine years, was admitted to hospital on January 2nd, 1923, on account of recurring attacks of haematemesis associated with severe epigastric pain. Melæna had been marked of late. Three years ago he commenced to have "hunger pains," which caused him great inconvenience, so that often he was unable to remain on duty. He was always conscious of some more or less intense upper abdominal discomfort. At times food gave relief, but sometimes it only intensified the discomfort. He had had many forms of treatment, but symptoms gradually became worse. He stated that he had vomited blood on four occasions during the three months before admission, but never in very large quantity. Vomiting had been troublesome, and recently the vomit had contained much mucus. There had been considerable loss of weight during the last year. Palpation showed marked epigastric rigidity, especially on the right side; there was also a very tender area above and to the left of the umbilicus.

The patient was put on intensive alkaline treatment on January 3rd. He quickly lost all his symptoms, was quite comfortable, and in about three weeks from the beginning of the treatment all signs of the ulcer had disappeared.

The X-ray findings are shown in Fig. 1 (a) (b) (c). In the first photograph (January 3rd) the X-ray report was "large penetrating lesser curvature ulcer low down." The next radiogram (January 19th) showed "a smaller crater low on lesser curvature." The third radiogram, taken on January 27th, showed a normal stomach with no appearances of ulcer.

The patient is quite well and has had no further symptoms.

#### CASE 11.

A boilermaker, aged 55, had suffered from stomach trouble for thirty years. He was admitted to hospital on January 16th, 1923, with a provisional diagnosis of carcinoma of the rectum. He was very anaemic and wasted, and showed marked cachexia. He stated that for over thirty years he had been "a martyr to indigestion," and "had tried all remedies, but without effect." Upper abdominal discomfort had been troublesome for several years. He had vomited frequently, especially during the last few years. Food nearly always made him worse. During the last six months his condition became so bad that he could scarcely get to his work. He thought his stools had been tarry. Marked tenderness and rigidity were present in the epigastrium, and his

general condition was very bad. Nothing was found in the rectum. A diagnosis of gastric ulcer was made, and a radiogram taken. The patient was put on intensive alkaline treatment, and soon obtained marked relief. He is now quite fit, and says that he has not felt like this for over twenty years.

The changes in the ulcer are shown in Fig. 2 (a) (b) (c). In spite of the length of his illness the ulcer healed completely in less than two months. The first radiogram showed "a large penetrating lesser curvature ulcer with much delay in emptying of stomach from antrum." The next one, taken about a month later, showed "crater" still present but very much reduced in size; local tenderness not present." The third radiogram, taken a fortnight later, showed the entire disappearance of the ulcer. These results, in a case of thirty years' standing, are certainly very striking. The patient has put on weight steadily and is now quite fit and well.

#### CASE III.

A police constable, aged 44, says he has had stomach trouble "ever since he was a young man," but that it generally improved when he went on to a milk diet. He has had several teeth removed at intervals during the last seven years as they were "bad." He states that he has suffered "indescribable agony" during the last five years whilst on duty, with a feeling of "hunger and emptiness." For this period he has never been able to get relief for more than a day or two, no matter what he took. Recently he has lost weight and his ordinary clothes are now much too big for him. The epigastric area was very tender and rigid. His general condition was bad, and he looked as if he had suffered a good deal.

He was admitted to hospital on January 29th, 1928. A radiogram taken the following day showed a large penetrating lesser curvature ulcer (Fig. 3, a). He was put on intensive alkaline treatment and almost immediately got relief from his symptoms. A radiogram taken on February 14th still showed a crater, but this was considerably smaller than before (Fig. 3, b). Another radiogram taken on February 23rd showed that the ulcer had entirely disappeared, the report being "no ulcer now seen" (Fig. 3, c).

This patient is now quite free from symptoms and is rapidly gaining weight.

#### CASE IV.

A married woman, aged 35, was admitted to hospital on January 2nd, 1928, on account of a long-standing dyspeptic condition

#### ALKALINE TREATMENT IN PYLORIC STENOSIS.

It might be thought that stenosis of the pylorus from old ulceration would not be much influenced by medical treatment, and that the aid of surgery should always be sought in such cases. Strangely as it may seem, intensive alkaline treatment is often of the greatest value in pyloric obstruction, and, if the symptoms are not too severe, a trial should

be given to this treatment before deciding on operation. In mild cases alkaline treatment often gives excellent results, and even in patients suffering from intermittent vomiting relief from symptoms may be obtained. In this connexion Sippy<sup>1</sup> remarks that

"Pyloric obstruction, even of the highest grade, and of long duration as evidenced by the presence of vigorous peristaltic waves showing through the abdominal wall, history of vomiting food eaten the day before for many months, the aspiration of food eaten twelve or more hours before, and the presence of abundant saucine, often rapidly disappears, so that at the end of ten days' or two weeks' management, seven hours after the largest and coarsest kind of a motor meal is given the stomach is found empty."

The reason for this wonderful effect of alkali depends on the fact that the obstruction is often due not to fibrotic changes alone, but to inflammatory oedema and spasm. Under the influence of alkali the spasm relaxes and the oedema subsides, so that a way is formed sufficiently large for the passage of food. I use this method in all but the most severe cases of pyloric stenosis, and generally with good results. Sometimes, indeed, the effect is really striking. About two years ago an elderly lady, aged 72, was admitted to St. Thomas's Hospital with all the usual signs of stenosis. She vomited two or three times a week, and

FIG. 2.—Case II. Showing changes in ulcer: (a) January 19th; (b) February 23rd; (c) March 6th.

FIG. 3.—Case III. Showing changes in ulcer: (a) January 10th; (b) February 14th; (c) February 23rd.

becoming so severe that she could not carry on her household duties. She gave a history of more or less troublesome indigestion for some ten to twelve years. She had had much nausea, together with pain, for which she could never get definite relief until recently, when she bought large quantities of patent alkaline preparations. When she went on to a very low diet she obtained some relief, but she always had a definite sense of discomfort. Her weight had got progressively less, and on admission she was thin and careworn, with much epigastric pain and tenderness. A radiogram was taken before the patient entered hospital, and the report was as follows: "Stomach a little low and showing no duodenal cap. Emptying is definitely delayed. Appearance of partial pyloric obstruction probably due to an old ulcer" (Fig. 4, a).

Treatment was commenced on January 3rd, and another radiogram taken on February 3rd. The patient's symptoms cleared up immediately and she is now quite well.

The report on the second radiogram (Fig. 4, b) was "general appearance much improved—emptying in normal time—a small cap now seen."

Many other similar results could be given, but the above will serve to show the extraordinary marked and rapid effects produced by this treatment, even in very long-standing cases with severe symptoms and marked x-ray changes.

food eaten twenty-four or thirty-six hours before was often found in the vomit. Peristalsis was observed through the abdominal wall, and it was obvious that the condition was passing on to a serious stage. An operation was suggested as the only means likely to help, but this the patient obstinately refused, and no amount of persuasion could induce her to yield on this point. Though it was thought that the case was much too severe for medical treatment, a trial was given to alkalis. In a short time all the symptoms passed away, and the patient could take a certain amount of food without discomfort. It is over two years since she had the treatment, and she has not vomited once during that time. Special inquiries made a fortnight ago elicited the fact that she is doing quite well and has no gastric symptoms.

In cases of mild stenosis the ordinary alkaline treatment as indicated above may be used, but in very severe cases with vomiting a slight modification, as indicated below, may be advisable.

FIG. 4.—Case IV. Showing condition of duodenum (a) on January 1st, (b) on February 3rd.

## ALLEGED DANGERS OF INTENSIVE ALKALINE TREATMENT.

No medical man need be afraid to use this treatment. In some patients it may give rise to slight symptoms, especially during the earlier stages, but generally these symptoms rapidly subside, and the system accommodates itself to the comparatively large amounts of alkali ingested. According to American writers, the chief symptoms encountered are, first of all, dryness of the mouth and throat, followed by headache, anorexia, nausea, and vomiting. There may also be mental depression and loss of energy. Analysis of the blood in some of these patients shows that the nitrogenous waste products may be somewhat increased, while there may be some interference with the "acid-base equilibrium" of the body. This so-called "alkalosis" following the use of very large doses of sodium bicarbonate has been described, among others, by Hardt and Rivers<sup>7</sup> in 1923, by Brown, Rusterman, Hartmann, and Rowntree<sup>8</sup> in 1923, by Ellis<sup>9</sup> in 1924, by McVicar<sup>10</sup> in 1924, by Houghton, Venables, and Lloyd<sup>11</sup> in 1925, and by Jordan<sup>12</sup> in 1926.

From a careful perusal of the literature on alkalosis it seems fairly clear that the medical practitioner need not fear in the slightest degree to use the intensive alkaline treatment as indicated here. That certain symptoms may occasionally appear is admitted, but they are exceedingly rare. Indeed, it is obvious that, in many cases where the symptoms were described, quite excessive doses of sodium bicarbonate were used. The exact dose is not always given, but where it is recorded it often amounted to about 30 grams a day over long periods. When the treatment is used as indicated here there is practically no risk of alkalosis in otherwise healthy people, and even if symptoms should intervene there is no harm done. If the patient complains of headache, nausea, vomiting, anorexia, and excessive dryness of the mouth it is quite easy to stop the treatment for a few days. So far, as already indicated, I have never seen anyone who had any symptoms. If followed on the lines indicated here the amount of sodium bicarbonate taken daily is too small to cause any damage in ordinary cases. That there may be some danger when the patient is suffering from chronic nephritis is admitted (see Stieglitz<sup>13</sup> and others), and the same may be true when very marked pyloric stenosis with excessive vomiting is present.

## SPECIAL TREATMENT IN PYLORIC STENOSIS.

In ordinary cases of mild pyloric stenosis with little or no vomiting, but showing marked x-ray changes, the ordinary alkaline treatment may be used. In severe cases, however, with excessive vomiting, there is practically no communication between the stomach and the intestine, and in such cases hydrochloric acid is constantly being lost to the body by vomiting. This results in a decrease of acid and a consequent relative increase of alkali, so that the body fluids may tend to pass to a more alkaline condition than normal. This "alkalosis" may be accompanied by severe symptoms, the most pronounced being tetany. If the symptoms are dependent on relative or absolute excess of alkali in the body, it is obvious that it might be dangerous to give more alkali, especially a soluble alkali such as sodium bicarbonate, for this would tend to make the condition worse. Theoretically we should really give an acid to make up for the acid loss.

Now in cases of practically absolute obstruction the giving of sodium bicarbonate could do no harm, for it could not get through into the intestine and so reach the blood. It would simply neutralize the acid in the stomach and then be thrown out, either as bicarbonate or chloride. From the stomach, absorption of sodium bicarbonate does not take place. It is true, however, that the effect of the sodium bicarbonate in neutralizing the acid might result in a subsidence of the oedema and spasm of the pylorus, so that some gastric contents might pass on into the intestine. At this stage an excess of sodium bicarbonate would tend to increase the alkalosis, and what we really want is something to favour acidosis.

Haldane<sup>14</sup> has shown that calcium chloride when taken by the mouth acts as an acid, and is equivalent in effect to giving hydrochloric acid, because most of the calcium remains in the intestine while the chloride is absorbed.

Gamble, Ross, and Tisdall<sup>15</sup> showed that about 40 per cent. of the chlorine of  $\text{CaCl}_2$  acted inside the body as  $\text{HCl}$ . Indeed, instead of causing an alkalosis the bivalent cations (calcium and magnesium) produce an acidosis in the body (McDonald and Godfrey<sup>16</sup>).

Therefore, in a case of very severe pyloric stenosis it would obviously be best to use as an antacid, not sodium bicarbonate, but calcium carbonate, or this along with magnesium carbonate. The carbonate would be changed into chloride by the gastric acid, and some of this would net as hydrochloric acid in the body, and so tend to prevent the drain of acid. That calcium carbonate acts quite efficiently as an antacid has been demonstrated by Loevenhart and Crandall.<sup>17</sup> The safest treatment for severe pyloric stenosis would therefore appear to be by means of a powder consisting largely of calcium carbonate with some magnesium carbonate to help the bowels. Teaspoonful doses of such a powder should be given on the lines indicated above for the ordinary powder. In addition to this, small doses of calcium chloride would help the alkalosis.

Generally speaking, the intensive alkaline treatment is not associated with any real danger under ordinary conditions, but the treatment must be carried out on the general lines indicated here, and the vastly excessive doses of sodium bicarbonate sometimes used should be avoided.

## DEBATABLE ASPECTS OF THE SURGERY OF GASTRO-DUODENAL ULCERATION.\*

BY

CHARLES A. PANNETT, M.D., B.Sc., F.R.C.S.,  
PROFESSOR OF SURGERY, UNIVERSITY OF LONDON; SURGEON TO  
ST. MARY'S HOSPITAL.

So long as the innate nature of gastro-duodenal ulceration is still ranked among the unknown phenomena of pathology there is bound to be disputation about the manner of its control. Controversy arises over many problems of the disease and its complications, but the greatest of these is the problem of the uncomplicated ulcer.

## THE NEED ON IMPROPRIETY OF SURGERY FOR THE UNCOMPLICATED ULCER.

It is most perplexing to read the writings of physicians and surgeons, for they are often directly contradictory in their views and recommendations; but their very discordance engenders the suspicion that the conclusions of the extreme enthusiasts of medical or surgical measures must largely cancel each other out, and that the truth lies somewhere between them. The relevant facts upon which alone a sound judgement can be based are simply stated.

(a) Ulcers of the stomach and duodenum can and do heal without the aid of surgery when conditions are favourable. This has been proved by actual visual inspection through a gastroscope,<sup>1</sup> by the x-ray disappearance of the ulcer niche under medical treatment,<sup>2,3</sup> and by the finding of the scars of ulcers after death at necropsy.

(b) Certain ulcers fail to heal with the most careful medical treatment, or they heal and break down again so that the symptoms recur. The number of ulcers which will heal without surgical help is large. It has been stated that *post mortem* as many scars as open ulcers are to be found.<sup>4</sup> But one pathologist discovered nine times as many scars as ulcers in the stomach.<sup>5</sup> This is the highest

\* A lecture delivered to the Kensington Division of the British Medical Association on March 23rd.

proportion of scars to open ulcers I have been able to find reported. Quite possibly scars in the stomach get overlooked at necropsy, and this higher figure more nearly approaches the truth. At any rate, it is certain that the tendency to healing is great. So a most important rule, to which there are a few exceptions, may be laid down: *No ulcer patient should be subjected to operation until medical treatment has proved a failure.*

It is pertinent to ask what proportion of ulcers respond to medical treatment. One observer, in 244 cases, found the percentage for gastric ulcer to be 62.5, and for duodenal ulcer to be 79.5.<sup>6</sup> These facts should be graven upon the mind of every operating surgeon. However, certain of these immediately cured cases will relapse. There are not many records of the late results of medical treatment. Forman,<sup>7</sup> in 32 cases followed up and subsequently x-rayed, found 57 per cent. failures. The number of permanent cures is certainly much smaller than the number of immediate successes. Is it possible to select those cases which will prove resistant to treatment? Several observers have said that there is no relation between the rate of healing and tendency to relapse and the length of history or size of the niche, but this last statement is open to doubt. When the niche is large, with a rounded extremity, healing is not so likely to occur or remain permanent, particularly as the gastric or duodenal wall in its neighbourhood is often fixed by the ulcer having invaded the pancreas and caused much surrounding fibrosis. Therefore it seems right to conclude that, while the tendency to repair is great, a significant percentage of ulcers cannot be induced to heal by medical means alone, and that of those that do heal a certain number break down again. It is thus justifiable to resort to surgical measures when medical treatment has failed, provided always that the mortality of operation is not too high—a consideration which will be dealt with in the next section.

#### CHOICE OF THE TYPE OF OPERATION.

Having decided that there is occasion for surgery, it will be necessary to select the type of operation. A simple operation, gastro-enterostomy, can alter local conditions in the stomach so that healing may be assisted; or more can be effected by the removal of the diseased part of the stomach, whereby the tendency to ulcer formation in the future is very greatly diminished. Both of these are indirect methods, though the latter is often spoken of as a radical procedure. To choose between these we must know how effective each is, and what is its accompanying mortality.

##### *Gastro-jejunostomy.*

In the case of gastric ulceration there have been a number of reports of what success gastro-enterostomy can bring. Emanating from all parts of Europe, from America, and from this country, they show a surprising agreement in all essentials. It is found that about 75 per cent. of open ulcers at the pylorus are made to heal, but only about 50 per cent. or less of ulcers away from this region. There can be no doubt at all that gastro-jejunostomy does not meet with really striking success in gastric ulcer, yet it would not be right to leave the matter here without asserting the fact that sometimes unexpectedly large ulcers have healed when this operation has been performed. It obviously has its place, and should be considered when other methods are either impossible or fraught with grave risk.

When we consider the use of gastro-jejunostomy in the treatment of duodenal ulcer there is no such general agreement. Thus Moynihan,<sup>8</sup> Walton,<sup>9</sup> Balfour,<sup>10, 11</sup> and Sherren<sup>12</sup> obtained complete cures in 85 to 92 per cent. of their patients. But other clinicians have not achieved anything like the same success. Wydler,<sup>13</sup> Forsyth,<sup>14</sup> Lewisohn,<sup>15</sup> Smithies,<sup>16</sup> and myself<sup>17</sup> can only count upon 50 to 70 per cent. of cures at most. The mortality of gastro-jejunostomy ranges from none in 500 cases (Moynihan<sup>18</sup>) to 8 per cent. by such a skilled operator as von Haberer.<sup>19</sup> It is bound to be higher in the statistics of those surgeons who reserve it for the worse risks, but I believe it fair to assess it at 4 to 5 per cent.

The liability to haemorrhage from a gastric, but particularly a duodenal, ulcer is about as great after an

operation as before. Perforation of a gastric ulcer may occur subsequently, but very rarely that of a duodenal ulcer, though this is not unknown. There is also a very definite incidence of gastro-duodenal ulceration, the frequency of which is estimated from 2<sup>nd</sup> to 18 per cent.<sup>15</sup> Sometimes a gastro-jejunostomy performed for duodenal ulceration will cause this lesion to heal, but subsequently an ulcer will form on the lesser curvature of the stomach. I have known this happen in 4 cases. Curiously enough, Rowlands mentions a similar case in a recent paper upon gastro-jejunal ulcer.<sup>21</sup> If we accept the hypothesis I put forward<sup>22</sup> as to the conditions favourable to the formation of peptic ulcers—namely, admixture of the duodenal with the pyloric secretions—it is easy to see how cure of the duodenal ulcer will lead to relaxation of pyloric spasm and so to duodenal regurgitation along the gastric sulcus once more during the later stages of digestion, a phenomenon which is absent when a duodenal ulcer exists. Conditions thus become favourable to ulcer formation on the lesser curvature.

#### *Resection Operations.*

We may now turn to the facts about resection operations. The properly conceived operation of this type not only removes the ulcerated area, but also takes away so much of the pyloric part of the stomach that the second stage of gastric secretion is very much interfered with, thereby lessening the disposition to further ulceration. I have knowledge more particularly of three types of such operations—the Péan resection, the sleeve resection, and the Moynihan variety of Polya's procedure. They all meet the requirements stated above, and are indicated in different circumstances. There are many reports of late results of resections for stomach ulcers (see references 13, 20, 23, 24, 25, and 26). The successes range from 70 per cent. to well over 90 per cent., most observers giving the higher figures. My own late results give 80 per cent. perfectly well. At any rate, it may be said that, with the same standard of cure, these resection operations give half as many good results again as gastro-enterostomy. It is widely held that a high mortality is associated with gastric resection, a very much higher death rate than with gastro-enterostomy. But this is not so. Amongst 59 gastric resections for ulcer I had 3 deaths. One of these, due to a technical fault at the operation, was preventable; the others were from lung complications, which are very imperfectly under control. This makes a mortality of 5 per cent. It is quite a serious mortality, but not so very high when it is remembered that 83 per cent. of all cases submitted to me had the resection operation performed on them, though many were in a poor condition from malnutrition or a previous severe haemorrhage.

Let us now turn to the much debated subject the resection of duodenal ulcers. At one time the removal of the affected segment of the duodenum was regarded as impossible;<sup>17</sup> but it was shown by the work of von Haberer, Flusterer, and Clairmont that this is not so. Some surgeons who claim good results from gastro-enterostomy at the same time recommend excision of the anterior ulcer when it is simple and easy. The operation of partial duodenectomy is not performed by many men because of the belief that it is an extremely dangerous one. I have done a partial duodenectomy for duodenal ulcer 61 times, with 2 deaths, both from lung complications. Moreover, this series includes the very first cases, in which the technique was anything but perfected. The mortality rate is, therefore, 3.3 per cent. I have only tried the operation in bad cases. Sometimes it cannot be done because the callous mass has extended too far down the duodenum; sometimes it seems undesirable because the ulcer is small and soft. So I have performed a resection in only 72 per cent. of cases. The results of the procedure have been much more satisfactory than those of gastro-enterostomy. Of 21 cases operated upon for more than two years 18 (86 per cent.) were perfectly well, in contrast with 69 per cent. by the latter operation. One other patient had such very slight symptoms that he may almost be regarded as a complete cure. Counting him, the percentage would be raised to 90. To ensure success, it is necessary to take away a sufficient portion of the pyloric region of the stomach; more than a simple pylorotomy must be done.

Having brought out the facts, it is now possible to adjudicate upon the question of operation in the uncomplicated ulcer. With few exceptions, every gastric ulcer patient should be submitted to a course of medical treatment. When, by proper rest, diet, and medication, the pain cannot be controlled, vomiting continues, and weight is lost, then surgery is indicated. If there has been a single haemorrhage of any volume in the past, and an ulcer can be demonstrated by the x rays, an operation should be carried out without a trial of medical measures. When a Haudek's diverticulum is large, with a rounded, blunt end, it is often wise to advise an operation, as relapse in many cases occurs. Finally, economic conditions may require that the patient should be got well with as little loss of time as possible. Perhaps he must work to live, or he is performing such valuable work for the community that his services can ill be spared. Such circumstances must be very carefully weighed before a decision to operate is made, remembering always that there is about 5 per cent. mortality associated with the procedure.

#### THE BLEEDING ULCER.

The controversy on this problem cannot be so easily dismissed as some surgeons would wish by accepting the statement of many of our medical colleagues that a patient seldom dies from such loss of blood. The truth is quite otherwise. Haemorrhage from a chronic ulcer of the stomach or duodenum is a serious menace to life. Bulmer recently, in 500 cases, reported a mortality of 8.3 per cent.<sup>22</sup> From our point of view the clinical course of the event is important. Sometimes the victim will die in a few hours from a single massive haemorrhage. He is at once beyond human help. More often he rallies from this first haemorrhage, but his immediate future is full of peril. Bleeding from an ulcer is of the secondary type and follows the characteristic course of this affection. The uncertainty of the arrest of haemorrhage is great; very frequently after a few days a further loss of blood occurs, and this may be repeated until the patient's strength is sapped to his extinction. Cannot ordinary surgical principles be applied to this gross complication? The answer is not quite simple to give.

Arrest of haemorrhage means a rather big operation which the patient may not be in a condition to stand, and this, combined with the undoubted fact that numbers of patients recover under expectant treatment, has led to the majority of surgeons deciding against operating. The mortality from it has been so high that it is held that the lives saved do not compensate for those lost when operation is adopted as a routine. Of late years, however, conditions have somewhat changed. Not only have operations upon the stomach become safer, but the transfusion of blood allows us to operate in circumstances which formerly would have proved fatal. Immediately a haemorrhage has occurred the patient falls into such a state of shock that any kind of surgical procedure is precluded. This shock, with its lowered blood pressure, is the natural method by which haemorrhage is arrested and clotting in the eroded vessels allowed to occur. When this has actually happened the patient can, with some degree of certainty, be considered safe for a few days. Therefore steps to combat the loss of blood, including a transfusion, should be taken. As the victim rallies from his shock an estimate of his general state should be made by observing the fall in pulse rate and estimating the percentage of haemoglobin in his blood. A pulse rate which remains over 100 means that there has been a very great loss of blood. Operation is risky, but is often possible. A patient with only 50 per cent. of his haemoglobin is in a very poor state to withstand a resection, but in favourable circumstances it can be employed. A blood transfusion will always be necessary in such a grave case. Local anaesthesia is regarded as essential by Finsterer, but I have employed only general anaesthesia, being somewhat afraid of the lowering of blood pressure which the splanchnic block produces. Once within the abdomen the type of operation must be decided upon. A partial gastrectomy or duodenectomy is the ideal, and should always be done whenever it is technically possible. Fortunately a resection by proper methods can now be performed with very little

further loss of blood. Sometimes it will be decided that resection is too dangerous; then the arteries supplying the ulcer must be tied, a procedure which may necessitate the opening of the viscera and ligation from within. A gastro-jejunostomy is useless for stopping haemorrhage from a gastric ulcer.

To sum up: Every case of bleeding from a gastric or duodenal ulcer should be looked at from a surgical point of view from the first. There should be a disposition to operate as soon as ever the condition of the patient will allow. Though the step is a serious one, the adoption of this policy, taking the precautions which I have mentioned, will save more lives than the pursuit of a solely expectant attitude. It is fatal to wait for successive haemorrhages before considering operative treatment. The patient will only be reduced to such a state of weakness that he is unlikely to stand it and survive.

#### THE PERFORATED ULCER.

The problem of the perforated ulcer is not whether an operation should be performed, but whether any other procedure should be added to the essential closure of the perforation. On the Continent operators have actually, of late, been performing typical resections of the stomach in cases of perforation—a development in gastric surgery so amazing that it must be passed in review. In this country there are many surgeons who hold that a gastro-enterostomy should be done at the time the ulcer is sutured. These surgeons claim that the anastomosis is frequently necessary because the suture of the ulcer leads to pyloric stenosis; they say that convalescence is smoother and the risk of the new suture line failing to hold diminished, as the stomach cannot become distended. They also make a great point of the fact that by doing a gastro-jejunostomy they are performing a curative operation upon the ulcer. What, once more, are the facts?

It is recognized that many ulcers which perforate are acute lesions, they have a different pathology from the chronic ulcer, and once the crisis is over conditions leading to the formation of such ulcers may never recur. Unless the technique is very clumsy the pylorus will not be obstructed by the in-turning of the stomach wall necessary to close the perforation.<sup>23</sup> It is also proved by late investigations<sup>24, 25, 26</sup> that many patients after simple suture are permanently cured and never again suffer from their ulcer. I believe that this recovery rate is perhaps overestimated and that the true percentage of cures is probably about 50. Gastro-jejunostomy is, therefore, unnecessary from this point of view in one-half of the patients; as a fine stomach tube will relieve distension of the stomach should blocking of the pylorus by the suture have occurred, it is not to be recommended on this account. Should the ulcer give trouble later another operation will be necessary, but it will not preferably be a gastro-enterostomy. The patient with a perforation is so ill that the less done to him the better. For this same reason I think resection in the presence of a perforation is not to be recommended. It would obviously be wrong treatment for an acute ulcer, and certainly too severe as a routine method for a perforated chronic lesion.

#### THE LATE CICATRIZED STOMACH.

When an ulcer has cicatrized it may leave the stomach with a narrow pyloric canal, or if it has been on the lesser curvature an hour-glass constriction deformity may result. Sometimes the two deformities occur together. When there is pyloric constriction alone a simple gastro-jejunostomy will often give an excellent result. The operation has its place, and should be done when there has been so much vomiting that the patient is dehydrated and is suffering from chloride starvation, which cannot be remedied by the injection of salt solution. In every other case I believe a Péan type of resection is preferable in pyloric stenosis. For hour-glass constriction, though a simple gastro-gastrostomy will frequently meet the case, I prefer a sleeve resection or the Péan operation. Chloride starvation must always be investigated in every patient in whom there is some defect in the passage of the contents of the stomach into the duodenum. It should be corrected before any serious operation is undertaken.

Surgery is not likely to say the final word in the treatment

of gastric ulcer. In the present state of knowledge it is the only method which brings relief to a number of victims of the disease. While such is the case there is sure to be controversy as to methods. I have striven to present these problems to you, and have suggested what I regard as the best solutions to them.

## THE TYPE OF TUBERCLE BACILLUS COMMONLY PRESENT IN TUBERCULOUS LESIONS IN BONES AND JOINTS.

Two Cases with Unusual Numbers of Tubercle Bacilli in the Discharges.

BY

LOUIS COBBETT, M.D., F.R.C.S.

(From the Department of Pathology, Cambridge Medical School.)

THE question whether tuberculosis of bones and joints is commonly caused by drinking milk from a tuberculous cow, or by inhaling tubercle bacilli derived from some human being, is, for the sake of prevention, not without practical importance. Yet it is one on which current medical opinion seems to be imperfectly informed, for, in conversation, one too often hears it taken for granted that such cases are usually caused by tubercle bacilli of bovine type. This is assuredly not the case.

The Royal Commission on Tuberculosis of 1901-11, Park and Krumwiede in the United States, and the committee of the Gesundheitsamte appointed in 1901 to investigate the rôle of the bovine type of tubercle bacillus in human tuberculosis, all agreed in finding that the tubercle bacillus present in the great majority of the cases of bone and joint disease which they investigated was of the human type. Cases from which the bovine type of bacillus was obtained occurred, but they were uncommon.

Then in 1912 came J. Fraser, who, having investigated 70 cases of tuberculosis of bones and joints in the Research Laboratories of the Royal College of Physicians in Edinburgh, came to the surprising conclusion that no fewer than 41, or 57 per cent. of them, yielded tubercle bacilli of bovine type alone; that 3 gave a mixture of both mammalian types; and that only 26, or 37 per cent., yielded the human type alone.

These findings were so different from those of all other observers, who agreed in putting the proportion of such cases infected with the human bacillus as high as 80 per cent. or more, that they were not received without criticism by bacteriologists who had worked in this field. Nevertheless, it seems that it is just these exceptional results obtained in Scotland that have attracted the attention of English physicians, rather than the far more extensive investigations made in this country.

It therefore seems worth while calling attention to the fact that A. S. Griffith, F. Griffith, and A. Eastwood, than whom no more experienced workers in this field (all trained in the school of the Royal Commission, 1901-11) could be

found, working for the old Local Government Board and the Medical Research Council, have made a most comprehensive study of the types of tubercle bacilli present in various kinds of human tuberculosis. This study, which has extended over twenty years, and, so far as bone and joint tuberculosis is concerned, embraces five different investigations, now includes close on six hundred (598) cases of this kind in which the type of tubercle bacillus has been fully determined.

This is the total dealt with by A. S. Griffith in his dissertation for the degree of Ph.D. Camb. in 1926. It includes 14 cases investigated by the Royal Commission, as well as a number in which the cultures were made, not from material taken directly from the bone or joint, but from some other lesion. For this reason I prefer to quote from a paper by the same author entitled "Tuberculosis of bovine origin in the human subject," read at the eleventh National Conference on Maternity and Infant Welfare held in London on July 5th to 7th, 1927. It deals with 541 cases of bone and joint tuberculosis, with the result that 81.3 per cent. of them were found to be caused by tubercle bacilli of the human type. This percentage refers to patients of all ages; if one takes only children under 5 years of age (102 cases), the percentage so infected naturally falls; but even here it is over 70 per cent. Under 10 years (327 cases) it is 75 per cent. This total includes a few cases from Scotland. These, in a somewhat earlier paper by the same author,<sup>1</sup> are separated from the English cases, with the result that a lower proportion of infections with the human type of bacillus is found in them than in those from England and Wales. The difference, however, is not great; for Scotland the percentage of infections with the human type of bacillus is 71.4 (28 cases), while for England and Wales it is 81.7 (389 cases). For children under 10 the corresponding percentages work out at 63.6 and 75.4 respectively.

### Frequency of Tubercle Bacilli of Human Type in Tuberculosis of Bones and Joints.

	No. of Cases.	Percentage w/ Human Type
All ages ... ..	541	81.3
Under 10 years ... ..	327	74.6
Under 5 years ... ..	102	70.6

### English and Scottish Cases Compared.

	No. of Cases.	Percentage w/ Human Type
Scottish cases, all ages ... ..	28	71.0
English cases, all ages ... ..	389	81.7
Scottish cases, under 10 ... ..	22	63.6
English cases, under 10 ... ..	288	75.4

Thus from this exhaustive and competent investigation we may conclude, indeed, that infection from the tuberculous cow is a good deal commoner in Scotland than it is south of the border. But it must be pointed out that the proportion of human infections in Scottish cases found by the English authors—namely, 71.4 per cent.—is very different from the 37 per cent. (or if we include the mixed cases, 41 per cent.) found by Fraser.

The fact is that bone and joint tuberculosis, commonly results from tubercle bacilli being transported to the part from some tuberculous focus (often a small and unsuspected one in some lymphatic gland) by the blood stream. In this respect it falls into line with other haematogenous kinds of tubercle—namely, with general tuberculosis, tuberculous meningitis, and genito-urinary tuberculosis, in each of which the proportion of infections caused by the human type of tubercle bacillus has been found to be in the neighbourhood of 82 per cent. In tuberculous meningitis it is even a little higher still.

It can therefore be stated positively that in England and Wales the great majority of cases of bone and joint tuberculosis are caused by bacilli of human type, derived from another case of human tuberculosis, and that they have nothing to do with the cow. Cases of bovine origin do indeed occur, and in very young infants constitute nearly a third of the total, but taking all ages together they do not amount to one-fifth.

It is interesting to note that in tuberculosis of the vertebral column bovine infections are rather commoner than in tuberculosis of the hip, and that in this latter condition they are somewhat more frequent than in tuberculosis of the knee. The higher incidence in the spine is

explained by Griffith on the ground that some of these lesions are caused by direct infection from the abdominal cavity, where, of course, as it is well known, the ratio of infection with the bovine to that with the human type of bacillus is high.

#### *Significance of Numbers of Tubercle Bacilli in the Discharges from a Tuberculous Joint.*

Two samples of pus from tuberculous joints which came to this laboratory attracted my attention on account of the unusual numbers of tubercle bacilli they contained. The severity of the disease turned out to be unusual also, and it seems that the numbers of bacilli in joint cases may have some prognostic significance. These cases, therefore, seem to be worth reporting.

A married woman, aged 38, was admitted to Addenbrooke's Hospital, Cambridge, on June 23rd, 1927, on account of severe pain in the left ankle. She came under the care of Mr. W. H. Bowen, to whom I am indebted for notes of the case. On admission there was a swelling on the outer side of the joint. This was aspirated five days after admission. The fluid then taken was sent to me on account of the numbers of tubercle bacilli, which were visible in stained films made from it. As is well known, the bacilli in such specimens are, as a rule, either few in number or not to be seen; but in this specimen they were so numerous that it was difficult to believe that one was not looking at a rich sample of tuberculous sputum; another unusual point was that there were well-formed pus cells present. Here was a case, then, worth investigating, and I proceeded to determine the type of the tubercle bacilli.

The clinical course of the case showed a disease of great activity. The history on admission was seven weeks only, and consisted chiefly of severe pain in the left ankle, especially at night. The joint appeared to be exquisitely painful on the only occasion that I saw the patient. Soon after admission it was immobilized on a poroplastic splint; but seventeen days later it was necessary to aspirate again, and 20 c.cm. of caseous fluid was then removed. The disease progressed rapidly, and it became imperative to amputate the limb. This was done forty-four days after admission. But though the wound healed the condition of the patient did not improve. On the contrary, she rapidly went downhill, and died of meningitis on November 11th, seven months after symptoms had first appeared in the joint. Tubercle bacilli were found a few days before death in cerebro-spinal fluid removed by lumbar puncture. Mr. Bowen writes: "The outstanding feature of the case was the rapidity of the process; also very noteworthy was the persistence of pain in the joint."

After death there were found marked signs of cerebral tubercle: excess of fluid, flattening of convolutions, tubercles in the basement membranes, dilatation of ventricles. In both lungs were some old fibrous scars at the apex, and here and elsewhere recent foci commencing to break down into little cavities with caseous walls; in the rest of the lung tissue diffuse military tubercles. A few minute tubercles were seen on the surface of the liver, but none in kidneys or spleen. The mesenteric glands and peritoneum were normal. The bronchial glands were much enlarged and beginning to show small caseating foci.

The original sample of pus, so rich in tubercle bacilli, had arrived in my absence, and I was unable to deal with it. Three weeks later I obtained a second, in which tubercle bacilli were present, but not in anything like the numbers originally seen, and pus cells were now absent. From this sample animals were inoculated and a culture raised from a tuberculous guinea-pig. The culture grew luxuriantly, and formed voluminous nodular growths on glycerin-potato and glycerin-agar, and, on suitable batches of glycerin-serum, it produced a yellow growth.

Four rabbits were injected intraperitoneally with 10 mg. of bacilli from young serum cultures. They were killed about four months later, fat and well grown. With one exception the lesions did not exceed those usual after such an injection of tubercle bacilli of human type—namely, a few little lightly encysted collections of caseo-purulent matter in the peritoneal cavity; but in one animal paralysis of the hind legs had occurred, and at the *post-mortem* examination a tuberculous lesion was found in one of the vertebrae, pressing on the spinal cord. Such a lesion is not unknown after injections of tubercle bacilli of human type into the rabbit; but Griffith and myself have met with it, and its presence in this case in no way weakens the conclusion that the bacillus with which we were dealing belonged to the human type. This strain of bacilli has since been used for many other experiments having a different object, and it has all along shown that low degree of virulence and inability to produce a progressive disease in the rabbit which is characteristic of the type. For the guinea-pig it proved virulent, and caused fatal tuberculosis.

The second case was that of a tuberculous wrist-joint in a man aged 69 years. As in the other case, it was the tubercle bacilli in the pus from the joint that first excited my interest in it; but they were not so numerous as in the first sample from that case. Some were seen in most of the fields; the largest number seen in any one field was five.

For the clinical history I am indebted to Dr. Christopher Tylor of Long Melford, Suffolk. The disease in the joint came on after a slight injury caused by jarring it severely when using an axe. About the same time the patient developed a cough, and had physical signs indicating tuberculous mischief in the lungs. The disease in the wrist-joint then became more acute, and there was evidence of fluid. Six months after the commencement he was sent to Addenbrooke's Hospital, Cambridge, where an operation was performed by Mr. Cooke, who let out a large quantity of pus, curetted the walls of the abscess cavity and the bones, and closed the wound without drainage. A few days later the patient returned to his home. After this the pulmonary disease advanced rapidly, and he died a few weeks after his discharge from the hospital. No *post-mortem* examination was made.

A culture raised from a guinea-pig inoculated from the pus showed all the characters of the human type, and produced voluminous nodular growths on glycerin-potato, wrinkled films on glycerin-agar, and pigmented growth on certain batches of serum.

Two rabbits inoculated intraperitoneally with 10 mg. of serum culture on September 22nd remained well, and when killed two months later were well-grown, fat animals, with no sign of tubercle beyond the usual little collections of caseo-purulent matter lightly encysted in a thin membrane (which one so frequently sees in the peritoneal cavities of rabbits injected with the human type of bacillus), and in one of the animals a little wedge-shaped streak of chronic tuberculous disease in one kidney.

There can therefore be no doubt that in this case, as in the other, the tubercle bacilli concerned were of the human type, and we may conclude that the fact that numerous tubercle bacilli are visible in stained specimens of pus from tuberculous joints is not inconsistent with an infection caused by bacilli derived from another case of human tuberculosis.

The unusually rapid course and the fatal termination in these two cases, selected only because there were large numbers of tubercle bacilli visible in the discharges, raise the question whether the presence of these bacilli in numbers such as these cases showed would justify a grave prognosis. One hesitates to draw this conclusion from two instances, but they at least call for further observations of cases of a similar kind.

## EARLY DETECTION OF TUBERCLE BACILLI IN SPUTUM:

### PRACTICAL METHODS OF OBTAINING SATISFACTORY SPECIMENS.

BY

SIR JAMES DUNDAS-GRANT, K.B.E., M.A., M.D.,  
F.R.C.S.,

LARYNGOLOGIST TO BROMPTON HOSPITAL FOR CONSUMPTION.

THE importance of the early detection of tubercle bacilli in the sputum has been most strongly insisted on by Dr. Chandler and by various correspondents in recent issues of the *British Medical Journal*. I can heartily endorse their views, and I propose, therefore, to describe some very practical means for applying them in cases of difficulty such as not infrequently present themselves.

In many of these cases in which the general clinical evidence is in favour of the diagnosis of tuberculosis the report on the sputum supplied by the patient is that no tubercle bacilli have been found. As often as not this is because a good specimen of the sputum has not been obtained. Many patients seem to be unable to eject the liquid from the bronchi, but involuntarily swallow and spit little more than frothy saliva from the mouth. By means of coaxing, and urging them to "shoot it out into the bowl" while the head is kept down over it, a better specimen may often be obtained. If this fails, an active cough reflex may be excited by getting the patient to sniff

the vapour of *oleum sinapis volatile* from the neck of a bottle (say a six-ounce medicine bottle) at the bottom of which there is about half an ounce of the oil. This gives off the vapour all the more readily if the bottle is warmed over a lamp. Two or three sniffs generally result in a good cough and the expulsion (with a little encouragement) of the ejecta from the larynx and trachea into the basin. The sister in charge of the throat room at Brompton Hospital is of the opinion that if this does not excite a cough there is probably no laryngeal tuberculosis. I cannot go quite so far as this, but I am sure that the procedure described has often given us a "positive" result when all previous examinations had proved "negative." In a recent case a history of syphilis led to a diagnosis of that disease as the cause of the hoarseness which was complained of, no bacilli having been found, but a sniff of the oil led to a cough and the expulsion of a small quantity of sputum, in which the bacillus was found in fair abundance. This procedure should, of course, not be preceded by anaesthetization of the nose or larynx.

Another method of value when by any chance the former fails is the *intralaryngeal injection*, by means of a syringe, of a few drops of the lotion we use for cleaning up the larynx—namely, a weak solution of sodium bicarbonate to which is added a little hydrogen peroxide. This is done under the guidance of the laryngeal mirror, and it often works well, but in some cases we are balked by the obstinate closure of an irritable larynx.

In a case of this kind I recently tried another process. The patient either could not or would not cough, and

failed to respond to the methods above described. I therefore applied to his case the principle of *transnasal instillation* used for the introduction of oily solutions into the larynx. The patient was seated with his head thrown back and his mouth wide open. He was instructed to pant in and out through his mouth and not to swallow. While he was doing this I gently syringed about half a drachm of the soda and peroxide solution drop by drop through the nose. A small quantity entered the larynx and started a cough which resulted in the expulsion of a little sputum into the basin. Tubercle bacilli were found, and the diagnosis established. The patient was not upset in the least, and reported himself later as feeling much better.

I have occasionally caught on the *laryngeal mirror* a little patch of sputum sufficient for staining purposes, if the patient coughed spontaneously or did so by instruction during the examination. The examiner does well to wear a muslin veil when practising this last method.

The administration for a few days of *potassium iodide*, if not otherwise contraindicated, is known to facilitate the expulsion of sputum, and my colleague Mr. Ormerod and I have made use of it for this purpose.

These processes have helped in many cases of doubt or difficulty, and I describe them in the expectation that others will find them useful. It need hardly be said, however, that they should not be practised without discrimination. The most appropriate cases are obviously those in which there is doubt as to the diagnosis, and in which, therefore, the disease has not reached an advanced stage.

## THE RESISTANCE FACTOR IN DISEASE:

WITH SPECIAL REFERENCE TO SEPTICAEMIA AND ALLIED CONDITIONS.

BY

JEFFREY RAMSAY, O.B.E., M.D., M.R.C.P.,

PHYSICIAN TO BLACKBURN AND EAST LANCASHIRE ROYAL INFIRMARY.

In January, 1927, I was called into consultation in a case of facial erysipelas. The patient, who was in *extremis* and who died some six hours later, appeared to have been an otherwise healthy and abstemious man, and his death drew attention to the unsolved problem: What is the true or chief factor in causing the death of a patient who is suffering from a septicaemic condition? The question was put to several medical colleagues, and the answers were interesting, if not very illuminating. One man replied that the cause of death was a profound toxæmia; another, that the centres in the brain were put out of action by bacterial toxins; a third gave it as his view that death was due to cloudy swelling of all the cells of the body; a fourth answered that he did not know, and a fifth suggested that death was due to a lack of resistance on the part of the patient.

Such diversity of opinion indicates the difficulty of the question at issue, and although we may theorize as to the cause of death, the majority of us must admit frankly that we can offer no certain explanation of it. But we are on safe ground when we say that death has resulted from the patient's lack of resistance to the effects of bacterial invasion. This is, of course, a self-evident fact. If his resistance had been all-sufficient, it is unlikely that he would have died.

"The patient seemed to have no resisting power" is a phrase that we have used, often wonderingly, when a previously healthy man has succumbed to some infection—when he has been poleaxed, so to speak, by a disease from which he might reasonably have been expected to recover. Six men may have lobar pneumonia, and one—often seemingly the healthiest prior to the illness—may die, while the remaining five recover. Or death may occur unexpectedly following an apparently successful operation for appendicitis, or from septicaemia following a normal childbirth in which no manual or instrumental interference was required.

What is this lack of resistance, this subtle  $x$  factor, which determines a dangerous downhill course or even a fatal issue?

I desire to put forward the hypothesis that our successful resistance to bacterial infection depends largely on the orderly response of certain of our endocrine glands—namely, the sympathicotrophic group comprising the thyroid, suprarenal, and pituitary, and the vagotrophic group comprising the parathyroids and the pancreas.

### EXPERIMENTAL CONSIDERATIONS.

Extirpation of the thyro-parathyroids produces a reduction in the phagocytic properties of the leucocytes in a normal man; extirpation in monkeys produces increased liability to infection, and in some animals, there is frequently a fatal result.<sup>1</sup> Extirpation of the suprarenals appears to be invariably fatal. With regard to the pituitary, Cushing<sup>2</sup> states: "My own impression has been that total extirpation often provokes a peculiar train of symptoms passing from cachexia to coma and ultimate death." Smith<sup>3</sup> says that if the pituitary gland of rats is sucked out by the buccal route an invariable syndrome occurs. In young animals there is cessation of growth, and in adult animals there is, *inter alia*, physical impairment with atrophy of the thyroid, parathyroids, and suprarenal cortex.

Since extirpation of one or other of these glands may produce such serious results, surely it is only sound common sense to assume that a severe infection in the blood stream, attacking each and every gland simultaneously, may produce a result which may easily be fatal. To swamp an endocrine gland with a potent toxin must surely cripple its function, sometimes to an extent which may be equivalent to extirpation.

In profound toxæmias or infections in childhood hæmorrhage may take place into the adrenal medulla, producing profound collapse, associated with convulsions, vomiting, and purpura, a fatal result generally occurring within twenty-four hours.<sup>4</sup> Elliott and Tucker have shown the lack of chromaffin substances in the adrenals of fatal cases of diphtheria,<sup>5</sup> and, in certain fulminating cases of cerebro-spinal meningitis, hæmorrhage into the suprarenals has been associated with the fatal termination.

Unless the infection is overwhelming in potency, the glands may withstand its effects to some extent and for some time, and may hold out until the invasion has been quelled successfully. But in certain individuals what appears to be a comparatively mild disease may be fatal, and I suggest that the following are among the explanations in many such cases.

(a) The patient may have started life with faultily constructed glands.<sup>12</sup>

(b) He may have a natural tendency to faulty balance in the endocrine glands. Cammidge,<sup>13</sup> working with Howard, has carried out experiments with mice, and has found that in some apparently healthy animals a low blood sugar is a recessive character, transmitted in accordance with Mendel's theory of heredity, and he suggests that it seems probable from the experiments that the hypoglycaemia is due to hyperfunction of the pancreas relative to the glands of the opposite group—that is, thyroid, suprarenals, and pituitary.

This hereditary dysfunction or lack of balance is interesting, since the percentage of sugar in the blood of the peripheral circulation appears to be similar under like conditions in all mammals. It seems not unreasonable, therefore, to suppose that human beings may exhibit similar hereditary tendencies to imperfect balance of endocrine secretions. Such endocrine imbalance would explain certain cases of diabetes mellitus in young children; it would explain also the tendency to diabetes as a racial or hereditary condition, and would, in my opinion, explain a low grade of resistance to infection in some young children.

(c) Some gross or, more usually, subtle toxin from the apices of the teeth, from the nasal sinuses, from the tonsils, from the digestive tract (as in alcoholism) or from elsewhere may have been at work, undermining the healthy activities of his endocrine glands. Such a condition may be cumulative in old persons and may account for senility, sometimes of premature type, also for the glycosuria which occasionally develops in later life, and for the ease with which elderly people succumb to acute infections.

(d) He may be the victim of unsuspected vitamin deficiency. McCarrison has shown that vitamin defects lead to endocrine changes; the adrenals and pituitary enlarge, while other endocrine glands show more or less atrophy.<sup>14</sup> Hence there must be a resultant imbalance. Pighini<sup>15</sup> has found that if tadpoles are fed on thyroid gland from pigeons in which beri-beri had been induced by an exclusive diet of polished rice, the tadpoles failed to show the acceleration of growth which is produced by administering the thyroid gland from normal pigeons. This suggestive experiment points to the assumption that a deficiency of vitamin B has a definitely inhibitory effect on the healthy functioning of the thyroid gland. For more than a century before the vitamin content of cod-liver oil was discovered the oil was used on account of its known beneficial effect in raising the patient's resistance, particularly to pulmonary affections.

(e) Emotional causes may lead to a disturbance of balance in the endocrine glands, as witness the well-known fact that cases of exophthalmic goitre showed a great increase during enemy air-raids on London. It seems reasonable to think that prolonged anxiety or psychological trauma of any kind may cause or be associated with endocrine imbalance. The gonads are sympathiotropic, and it is possible that sexual affairs may play a part in producing such an imbalance.

(f) Exposure to cold and damp and other adverse climatic conditions, such as lack of sunlight and fresh air, may cause a lowering of resistance and allow of the advent of certain diseases. In this case it is possible that impulses may pass from the nerve endings near to the surface of the skin and produce imbalance by way of the sympathetic nervous system. It is well known that in hyperthyroidism there is an intolerance to heat and in hypothyroidism to cold.

The position may be summed up in the words of Langdon Brown: "The balanced life is like a well-planned herbaceous border—to each season its appropriate flowers. For the due ordering of this we are much beholden to the endocrine system." I believe that the simile may be carried a stage further—if a sudden storm sweeps down on the herbaceous border there is an equally sudden strain thrown on the endocrine glands to stand up to the emergency.

Having outlined certain experimental points in connexion with the theory of endocrine resistance, I wish to mention some clinical details; but before doing so it is desirable to touch on physiological and other features associated with the two groups of endocrine glands.

1. The sympathiotropic group, katabolic in function, comprises the thyroid, suprarenal, and pituitary, and this group responds to invasion of an external foe by activating fight or flight, and of an internal foe (bacterial invasion) by pyrexia and other reactions. It is clearly recognized that these glands, associated with the sympathetic nervous system, are therefore concerned with the activation of the body for defence.<sup>16</sup>

The chief secretory impulses of the thyroid are under

the control of the sympathetic nervous system, but it is innervated also from the superior and inferior laryngeal branches of the vagus. It alone of all the secretions of the body contains iodine.<sup>9</sup> Thyroid secretion accelerates the heart without augmenting the strength of the beat; increased secretion diminishes sugar tolerance and may raise the basal metabolic rate. It is well known that hyperthyroidism may follow sepsis in tonsils or teeth in adult life. Adrenaline stimulates the force and frequency of the heart-beats, raises the blood pressure, and may excite glycosuria, because it tends to empty the glycogen reservoirs of the liver.

The anterior portion of the pituitary gland is concerned chiefly with the mechanisms of growth, and it is believed to influence the basal metabolic rate. As regards growth, it is interesting to note that when a child has recovered from some acute infection its bodily growth is often thought to have been accelerated, a point which suggests a stimulation of the anterior portion of the pituitary gland.

Dott<sup>17</sup> considers that the hypothalamic region of the brain, which has been called the head ganglion of the sympathetic nervous system, acts in conjunction with the anterior portion of the pituitary gland in its metabolism-regulating function. The internal secretion of the posterior portion of the pituitary gland has the property of slowing the pulse and raising the blood pressure. It appears to have a balancing effect on carbohydrate metabolism, inhibiting, for example, the effect of drugs which tend to change the blood sugar concentration away from normal in either direction.<sup>18</sup> Its overaction leads to glycosuria, and stimulation may play a part also in raising the basal metabolic rate.<sup>16</sup> It appears to be an antidiuretic, and its action on uterine and other muscle is well known.

It will be noticed that little mention has been made of another set of endocrine glands—namely, the gonads, which are linked up with the sympathiotropic group. Extirpation of the gonads, or their dysfunction as a result of disease or involution, may and does cause certain disturbances in the body processes, but I am unable to produce evidence that they play any important part in resistance to acute infection. For a similar reason no mention is made of the pineal body.

2. The vagotropics glands, anabolic in function, comprise the parathyroids and the pancreas.

Vines's<sup>17</sup> work has emphasized the importance of the parathyroids. He has demonstrated that parathyroid substance is a physiological adjuvant to the normal mechanisms of defence, and he states that there is some evidence that the production of antibodies may depend on the functional integrity of the parathyroid glands. He has shown that the calcium content of the blood is lowered in infective conditions. The parathyroid glands probably act as regulators of calcium metabolism, and, further, the giving of parathyroid gland may raise the polymorphonuclear leucocyte count in infections. The extract has a sedative effect on the nervous tissues; its diminution may lead to irritability, restlessness, and even to tetany.

The pancreas is probably activated, to some extent at least, by the parathyroids, and in the present connexion it is only of moment in relation to its function in helping to raise sugar tolerance.

#### CLINICAL ASPECTS.

I wish now to consider the clinical aspects of a patient who is in the early stages of an acute infection such as puerperal or other septicaemia, and to correlate the signs and symptoms with special reference to the sympathiotropic and vagotropic glands.

I desire to stress the point that the first effect of a severe bacterial invasion is a stimulation, obviously protective in character, of the sympathetic nervous system, in relation to which are the sympathiotropic glands. At the same time there is an inhibition of the vagotropic group, which may be actually paralytic in character—that is, it may result from imperfect response in these glands—or it may be a relative effect, by which I mean that the vigorous response of the sympathiotropic group may swamp the activities of the vagotropic group, thus causing imbalance in the whole endocrine mechanism.

Side by side with the clinical findings at an early stage of the infection I tabulate the findings in a case which is rapidly approaching a fatal termination.

Clinical Findings:	Early.	Late.
Facial aspect ...	Usually flushed	Pale or cyanosed.
Skin ... ..	Hot and dry, but sometimes perspiring	Cold and clammy.
Musculature ...	Movements may be strong and may even require restraint	Limp. Feeble, irregular movements may occur.
Mental state ...	Variable, sometimes clear, often delirious	Usually lethargic.
Temperature ...	High and swinging in type	May fall suddenly before death.
Pulse ... ..	Rapid, generally regular	Rapid, frequently irregular.
Respiration ...	Rapid and regular	Rapid and shallow, with irregular sighing before death.
Blood pressure ...	Slightly above normal for patient's age	Low.
Urinary secretion	Merging from normal to scanty	Scanty.
Basal metabolic rate	Raised	Not determined, owing to seriousness of patient's condition.
Sugar tolerance ...	Tends to be lowered	Blood sugar immediately before death averages 0.15 per cent. (see below).
Blood calcium ...	Lowered	—

As examples of the initial stimulating effect on the thyroid it may be noted that the face is flushed, the pulse and respirations are rapid, the basal metabolic rate is raised, and the sugar tolerance is lowered.

The tendency towards raised blood pressure seems to point to stimulation of the suprarenals, and their increased secretion may also be a factor in producing the rise in blood sugar. It has been said that the pituitary plays a part in connexion with the regulation of the basal metabolic rate, and the increased functioning of the posterior lobe of the pituitary may be one factor in the scanty urinary secretion.

The question of fever in connexion with the endocrine glands, calls for some comment. The mechanism of the production of fever is by no means certain. It seems likely that the heat-regulating centre resides in the tuber cinereum, and that this centre is stimulated as a result of bacterial invasion. Fraser<sup>10</sup> states that fever is now believed to be closely associated with hyperthyroidism due to the reaction produced in the thyroid gland by toxins. Langdon Brown<sup>11</sup> points out that fever increases the secretory activity of the adrenals and thyroid. This floods the blood with sugar, the increased oxidation of which increases the production of heat, and if the oxidative mechanisms are intact glycosuria is not excited. Miller<sup>12</sup> states that increased adrenaline inhibits loss of heat, and it follows that such suprarenal activity would be of great use in the initial stages of an acute infection by raising the internal temperature to a point unfavourable to the growth of micro-organisms in the blood and other tissues. The low blood calcium and low sugar tolerance point to inefficient functioning of the vagotropic glands.

Turning now to the signs and symptoms which accompany the approach of a fatal termination, many features seem to indicate a failure of glandular activity. The drop in blood pressure points to cessation of suprarenal secretion, perhaps with that of thyroid and post-pituitary.

It is a significant fact that limp musculature is an outstanding event, prior to death, in experimental removal of the pituitary gland. There is also, of course, the important fact that, in an acute infection, the muscles themselves have been inundated with the toxins produced by the invading organism. But may not this muscular condition be due in part to failure of the suprarenals to supply a substance acting on the myo-neural junction and maintaining muscle tone in normal circumstances? The irritability and restlessness may be due in part to parathyroid failure as well as to the direct effect of the toxin on the brain cells.

Dr. E. L. Carter, one of the resident staff of the Blackburn Royal Infirmary, is carrying out observations on the blood sugar immediately prior to death. His work is

not yet published, but he allows me to say that his average figure at present is 0.15 per cent. in patients dying from such conditions as lobar pneumonia and septicaemia. This is an isolated figure, as it is impossible, for obvious reasons, to carry out a complete sugar-tolerance test in a dying patient.

The points which have been mentioned are not convincing, but they are suggestive if they are regarded in an unbiased way. I do not for one moment imply that the sole cause of death is to be found in the failure of endocrine glands, but merely that these may play a highly important part, which may have been hitherto insufficiently stressed in relation to treatment. What of the heart itself, and what part does essential heart failure play in determining the lowering of blood pressure and a fatal result?

Pembrey<sup>21</sup> points out that the heart is very susceptible to a rise of temperature and malnutrition. Perhaps this malnutrition may consist in a lack of normally balanced constituents of the blood, so that the heart, like other muscles, is thereby enfeebled. In this connexion it is interesting to note that adrenaline actually dilates the coronary vessels in spite of its general vaso-constrictive action. If the blood supply to the myocardium is thus increased by dilatation of the coronary arteries this may explain to some extent the prompt action of intracardiac injection of adrenaline when the heart has apparently ceased to beat. If adrenaline is lessening in the blood during the later stages of an acute infection the coronary arteries will fail to allow of the passage of an adequate blood supply. Further, it is possible that the blood which does reach the myocardium is wanting in other constituents which should normally be supplied by the endocrine glands.

Many physicians consider that digitalis is of little use as a heart stimulant during an acute infection such as pneumonia. As Mackenzie<sup>22</sup> said: "The factors exciting the heart, such as high temperature, toxins, or the invasion of the heart by specific organisms, exert an influence over the heart which digitalis cannot overcome."

The modern tendency is to combat heart failure in these and other conditions by such substances as post-pituitary or suprarenal extract, and in this way we may be feeling our way towards the right path. Indeed, it is possible that when such a remedy succeeds it may do so, in part at least, by supplying a specific deficiency in the blood. One medical friend of mine to whom I had mentioned this matter treated a moribund case of lobar pneumonia with massive doses of thyroid extract, and to his astonishment the patient recovered.

To make use of an everyday expression, it is no good blaming the carburettor for the faulty running of an engine if the real cause of the trouble is petrol which is inadequate in character.

It is possible that the liver may play a not inconsiderable part in resistance to acute infection, but the means for assessing hepatic function in such a condition are somewhat inadequate. In like manner I know of no explanation, which has been proved hitherto, as to why the phagocytes flag in power under certain conditions, and I suggest that this may be due to deficiency of endocrine gland secretions in the blood stream. Reference to this point has already been made in connexion with the parathyroids. As regards agglutinins, opsonins, precipitins, and bacteriolysins, Dudgeon states:<sup>23</sup> "Unfortunately the presence of all these substances, even in large amounts in the blood, is not necessarily an indication of the patient's resistance to a bacterial invasion."

If, then, it can be accepted that exhaustion and failure of many of the endocrine glands may be an important factor in allowing the patient to be overcome by the invading organism, I submit that it is a rational procedure to supply him, from the beginning of the infection, with gland products to aid the tissues in their fight.

I suggest that the initial stimulation of the thyroid, parathyroids, and suprarenals throws a sudden strain on these glands, and it has been pointed out that the glands may be faulty from congenital causes, from the effect of toxins, or as a result of avitaminosis and other factors. We have little means of estimating the efficiency of the glandular response until the time of testing comes. They

may fail or they may withstand the strain, but it is hardly safe to wait. An acute appendicitis may subside without the surgeon's aid, yet it is usually more prudent to call for that aid. By supplying gland products we attempt to reinforce the natural defensive mechanism and thus to prevent its exhaustion. Just as insulin may be said to rest an overstrained pancreas, so other glandular extracts may co-operate with the natural secretions and allow them to continue their work without depletion of their strength. In the words of Vines:<sup>18</sup>

"The aim of treatment should be fundamentally to encourage the re-establishment of normal conditions (that is, a metabolic balance), and since the endocrine glands are the regulators of normal metabolism it is to them that we should look for a means of obtaining the end in view."

Geikie Cobb has called these the glands of destiny, and it is probable that the personality or "make-up" of each member of the human race is influenced profoundly by the predominance of one or more of the endocrine glands. This implies that there is an endocrine balance which is normal for each individual, though differing widely in different individuals; and I believe that health depends upon the maintenance of that normal balance, with slight but constantly occurring deviations according to the needs of the moment.

Departure from health, on the other hand, probably depends on, or is associated with, an unusual deviation from the normal balance. The compass is deflected more or less violently. If, for some of the reasons which have been given—for example, faulty diet or long-continued emotional strain—the endocrine glands become temporarily inefficient, acute disease may result from the advent of a virulent organism in the system, which then responds well or badly, according to the underlying condition of the endocrine glands. If the latter are only slightly under-

mined as regards their efficiency, they will respond adequately to the sudden stimulus of an acute infective condition, in which case recovery is likely after a struggle. An example of this is lobar pneumonia. If the endocrine response is poor, death is probable. Even if the invading organism is one of comparatively mild virulence, death may result if the endocrine glands are inefficient. An example of this would be the occurrence of boils, or a scratch on the skin, followed by septicaemia in a sufferer from diabetes; or the occurrence of puerperal septicaemia in a patient with apical infection of the teeth, presupposing that no interference with the normal course of labour has been necessary.

According to this view subacute and chronic diseases represent varying degrees of virulence in attack, balanced by varying degrees of endocrine response in defence. Having set forth the theory, I am carrying out work at present in connexion with its application to treatment in acute infective conditions.

## SIMPLE ILEO-CAECAL LYMPHADENITIS.

BY

C. JENNINGS MARSHALL, M.D., M.S.,  
F.R.C.S.,ASSISTANT SURGEON, CHAMBER CROSS HOSPITAL, AND VICTORIA  
HOSPITAL FOR CHILDREN.

THE subject of mesenteric lymphadenitis has from time to time attracted attention, probably, however, not to the extent it merits. Considerable confusion still exists apparently, to judge from the writings that appear now and again, as to the forms in which the condition occurs. The disease may be purely tuberculous, purely non-tuberculous, or a mixture. Tuberculosis of the glands may be diffused, but much more frequently is localized to the ileo-caecal angle; its late effects here, particularly as a cause of obscure chronic right-sided pain, are familiar to all. It is not uncommon to find a septic exacerbation of the process, just as is so often seen in connexion with cervical adenitis.

It is desired here to call attention to the existence of a simple adenitis, which may be either an acute inflammation or a chronic hyperplasia. Occasionally a chronic hyperplasia is found throughout the mesentery of the small bowel—usually in younger children affected by some definite chronic enteritis; much commoner, however, is the condition here described, which is localized to the ileo-caecal lymphatics.

## CLINICAL FEATURES.

The disease is seen chiefly between the ages of 5 and 15, and is more frequent in girls. Acute attacks may or may not have been preceded by other acute attacks or by chronic abdominal symptoms—for example, dyspepsia. A large proportion of patients conform to type: the child is a "finicky" feeder, is listless, easily tired, sallow, is liable to acidosis; the musculature is hypotonic. There is sometimes antecedent bowel irregularity, and acute attacks may be preceded by a definite catarrhal condition. It is notable also that a considerable proportion show cervical gland hyperplasia in addition; frequently there has been tonsillar trouble, as if the "stopping power" of the (alleged) first line of lymphatic defences of the mucosae were in general deficient.

## Acute Attacks.

The pain is rapid in onset and nearly always right-sided, but sometimes is epigastric or diffuse at the beginning. Vomiting and nausea are relatively infrequent; the appetite may be retained throughout, and the tongue remains moist and only slightly furred. Fever is early and often much higher than in appendicitis, not uncommonly reaching even 102° to 103° F. The bowels may be loose or constipated; the breath often smells of acetone. True abdominal rigidity is not found, though the right side may not move freely; deep tenderness is present over a band about an inch wide under the outer and middle part of the rectus muscle, above McBurney's point. Swollen glands are commonly palpable with a conscious patient, practically always under anaesthesia. Pain is often elicited by either active or passive movement of the hip.

The disease is as rapid in recovery as in onset: two or three days usually sees it end, while the pain itself may last only a few hours. It will be obvious that while there is a superficial resemblance to appendicitis, the two conditions are sharply cut clinically.

## Chronic Cases.

The patient comes under attention for repeated attacks, usually very short, of abdominal pain; there may be dyspepsia, and the case usually agrees with the type already described. The pain may be right-sided, umbilical, or epigastric; there may sometimes be persistent aching, worse on movement, on the right side. In a great number of cases the lumpy glands can be felt—the patient has a thin lax parietes; only slight tenderness is present.

## PATHOLOGY.

The glandular condition is localized to the ileo-colic chain, and affects the ileo-caecal group in particular. In some cases glands were enlarged up to and in contact with the duodenum, and the lowest were commonly adherent in the ileo-caecal angle; nodes are frequent on the anterior and posterior aspect of the ileo-caecal junction, and in the meso-appendix. In the acute cases the swelling is considerable, the retroperitoneal tissue is oedematous and abnormally vascular, and there may be a small amount of clear colourless fluid in the peritoneal cavity. In the chronic cases the glands are firm, nearly always discrete,

and rarely larger than a filbert. There is never any evidence of peritoneal thickening or adhesion over these glands, as is so common in tubercle, nor are there visible the whitish or yellowish patches of that disease. The glands are semitranslucent, fawnish or grey, never white; there is never caseation or suppuration. The total number of nodes is not greatly increased, as is so characteristic of tuberculous, nor is there dense periadenitis. On section the glands are homogeneous and firm: in acute cases they are oedematous and exude fluid, and show microscopically all the signs of acute inflammation; in chronic cases there is simple hyperplasia. Culture in two acute cases gave a growth of *B. coli*; in many, however, it was negative. All cases easily pronounced non-tuberculous on the above appearances were confirmed microscopically.

The bowel was carefully inspected in all cases, but in none was there any external evidence of ulceration, inflammation, or hyperplasia of submucous lymph nodes. In one case with intense glandular swelling the terminal two inches of the ileum and the caecum were intensely and uniformly glistening and rubbery, with the appearance seen after reduction of an intussusception—the condition was clearly one of lymphatic obstruction, and a result, not a cause, of the glandular disease. In general there is no gross appendicular disease (and it may be stated that manifest appendicular infection—for example, suppuration—is not associated with such glandular swelling as here described). Very constantly, however, there is a diffused, swollen, succulent condition of the mucosa, slight polymorphonuclear infiltration, and lymphoid hyperplasia, at times considerable. Other abnormalities—oxyurides, soft faeces, submucous fibrosis—were fairly common, but did not appear relevant.

#### PATHOGENESIS.

Once again it must be insisted that this disease is not tuberculous, and occurs chiefly in a very distinct type of patient, whose mucosae offer but poor resistance to the passage of bacteria and in whom exacerbations of infection are apt to precipitate attacks of acidosis. That the incidence is chiefly on the ileo-colic glands would suggest the altered nature of the bowel content in this region as a determining factor. No confirmation of a catarrhal disease of the caecum was obtained by microscopy of a small portion of this excised with the appendix. There is, however, another possibility: it is commonly said that lymphoid tissue, wherever found, is defensive, a barrier to infection; applied to submucous nodes, such a view is certainly open to the gravest objections, the structure of some such masses in particular giving the impression of being designed to favour the entrance of bacteria into the system. The appendix, by its structure, invites infection, and by its nature causes stasis and enhancement of bacterial virulence. In a large proportion of cases, but admittedly not all, treated by appendicectomy there has been not only cure of the symptoms but also a considerable improvement in general health. Treatment by intestinal antisepsis has been quite valueless, but, in view of their general inefficacy, perhaps the argument fails to carry weight as to whether or no the bowel is the source of the infection. The production of the acute attacks of pain may perhaps excite curiosity; it seems probable they may be vascular or neurogenous in origin, owing to the intimate relationship of the diseased structures to the neuro-vascular supply of the gut. In a recent case of acute adenitis it was seen at operation that irregular peristalsis had been excited, for, in addition to pronounced glandular disease, there was the beginning of an intussusception in the terminal ileum.

A protest should be registered against the widespread, rather happy-go-lucky "child will grow out of it" attitude; chronic infections in childhood may be the cause of grave damage, which may not become apparent until the stresses of middle age find the viscera exhausted; and it should be remembered in this particular instance that the infected lymphatics, as has long been known, are capable of inducing disease in such organs as the pancreas, gall-bladder, and pylorus.

#### TREATMENT.

In the acute cases, though recovery is invariable without intervention, and the diagnosis from appendicitis is usually

easily made, it will nevertheless often be felt that operation is safest, if only to put the diagnosis beyond doubt. In such instances the appendix will be removed.

In the conservative treatment of both acute and chronic cases the mouth and throat are put in order, the bowels are regulated, and the diet modified—green vegetables with plenty of roughage seem to exercise more influence than any other dietetic factor. If there be acidosis both sugar and alkali are necessary. A fair trial may be given to these and other general hygienic procedures (in my experience seaside air, sunlight, etc., have proved disappointing in these cases). A very considerable proportion of patients resisting such treatment will be cured by appendicectomy, and the opportunity can be taken to verify the non-tuberculous character of the case by microscopy of a gland. This again needs emphasis, as there seems to be an ineradicable general impression that all enlarged abdominal glands are tuberculous.

#### STATISTICAL SUMMARY.

Total cases 48; average age 10 years. Females 74 per cent.

*Acute Cases* (8).—Duration of symptoms three and a half days (average). Culture of *B. coli* from glands in 2 cases.

*Chronic Cases*.—Average duration of symptoms ten months. The patient conforms to type in about 75 per cent. Pain purely local in 72 per cent., on walking in 20 per cent. Glands felt without anaesthesia in 74 per cent. Constipation in 52 per cent.; occasional diarrhoea in 15 per cent. Tonsils removed in 17 cases. Urinary culture negative—9 female cases. Cases operated on 28; oxyurides in appendix in 6 cases; culture of glands always sterile.

*Results*.—Cases difficult to trace. In those followed, cures with great improvement in general health noted from six months up to five years. Four recurrences after operation—in one case there were several attacks during the first month after operation, none since; one case had several attacks up to two years after. Dental caries: one case (referred to under "Pathology") in which a large glandular mass was removed; this was actually said to be sarcoma by one pathologist. A painful attack occurred three years later; this seemed to be partial obstruction, possibly due to adhesions from the operation.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### SARCOMA OF THE STOMACH.

MR. JAMES S. HALL's report on March 10th (p. 393) of a case of sarcoma of the stomach which clinically simulated a duodenal ulcer has led me to consult the records of an undoubted case which came under my observation.

Although the condition is said to be extremely rare, another case was recorded on January 22nd, 1927 (p. 139), by Mr. H. Stewart Brander. In both these instances symptoms pointing definitely to stomach or duodenum were prominent features, whereas in the case I saw the symptomatology was entirely different.

A young man, aged 20, pale and listless, had begun three months previous to admission to have twinges of pain in the abdomen. This pain was in no way related to the taking of food; he had had no sickness, and his appetite was good. He was found to have a tumour mass about the size of a man's clenched fist in the left hypochondrium and extending into the epigastrium. The tumour was slightly movable, and was not notched. He had been sent in with a diagnosis of abdominal tuberculosis, but in appearance he looked more like a patient with a grave blood condition, and the position of the swelling seemed to support this. A blood examination gave a haemoglobin percentage of 70, with 4,500,000 erythrocytes and 12,000 leucocytes, a differential count revealed no abnormal elements.

One month after admission the abdomen was opened by Mr. James Taylor. A large tumour mass was found involving practically the whole of the stomach wall save for small portions at the cardiac and pyloric ends. It was adherent to the pancreas and to the under surface of the liver, and numerous omental masses were present in the gastro-hepatic and gastro-colic omenta. Removal of the growth was attempted, but was found impossible; a small portion and an enlarged gland were taken for pathological examination. Sections revealed small round cells of a typically sarcomatous nature with very little surrounding stroma. I for-

warded part of the specimen to Dr. R. M. Buchanan, city pathologist, who independently diagnosed it a sarcoma.

The patient remained in hospital for two weeks after operation, and during that time his appetite remained good; he had no nausea or vomiting, and little discomfort save for spasmodic attacks of abdominal pain. His anaemia rapidly became worse till the haemoglobin percentage had fallen to 30, with about 2,000,000 red cells; the anaemia remained of a simple secondary type. He died three weeks after going home.

Apart from the rarity of the tumour the case is interesting because of the entire absence of digestive disturbances, which may be explained by the fact that the neoplasm, originating, as such tumours are said to do, in the submucosa, spread outwards in the middle coat and did not apparently cause ulceration of the mucosa. The other two patients mentioned had definite digestive symptoms, but ulceration was present.

ALEXANDER SMITH, M.B., Ch.B.

Robroyston Hospital, Glasgow.

#### TREATMENT OF RECTAL PROLAPSE BY INJECTION.

WHILE the treatment of haemorrhoids by the injection of carbolic acid and hamamelis, or of other preparation, is well established as a surgical procedure, little or no attention appears to have been directed to this form of treatment for the cure of prolapse of the rectum. A considerable number of cases have now been treated by me, or under my supervision, in this manner, with satisfactory results. The following case, treated and reported by Dr. A. Briggs, my resident house-surgeon at the Eastern District Hospital, may be given as an example.

A man, aged 66, was admitted in November, 1926, complaining of pain, and a feeling of something coming down the back passage on defaecation, of ten years' duration. Examination revealed a rectal prolapse which protruded on straining for fully two inches beyond the anal margin. Patient was also suffering from chronic bronchitis and double inguinal bubonoele. Once a week for six weeks the wall of the prolapsed rectum was injected with carbolic acid and hamamelis, starting with a dose of 1 c.cm., and increasing to 2 c.cm. The patient was discharged at the end of December without prolapse. He reported in March, 1928, that the bowel had given no further trouble, and did not come down.

In this case, then, six injections were sufficient to remove a condition of ten years' standing, and it has not recurred for over a year, notwithstanding the patient's poor general condition and cough.

The treatment is carried out with even greater ease than the injection of haemorrhoids, since no speculum is required and, so far as one can judge, with less pain. Care should be taken to return the prolapse after injection, and it is generally well to give one or two final injections after the mass no longer comes down, using a speculum, if necessary.

JOHN A. C. MACEWEN,  
M.B., Ch.B., F.R.F.P.S.,  
Surgeon, Glasgow Royal Infirmary  
and Glasgow District Hospitals.

#### APPENDICITIS AND HEPATIC ABSCESS.

IN view of the case reported by Drs. W. A. Barnes and L. V. Pearson on March 10th (p. 390) the following details may deserve recording.

A married woman, aged 25, was sent to the Royal Lancaster Infirmary on December 28th, 1927, by my colleague Dr. E. Dockray, suffering from appendicitis.

I removed an inflamed and much swollen appendix through the usual paramedian incision. The patient ran a temperature for a few days and complained of epigastric distension, but otherwise made an uneventful recovery and was discharged on January 21st.

A few days after her return home Dr. Dockray was again called in and found her complaining of recurrent attacks of indefinite abdominal pain, which finally settled in the epigastrium. There was frequent hiccup, which lasted sometimes for hours. Her temperature ranged between 99° and 101° F., and the pulse between 84 and 120. I eventually saw her with him on February 4th, and it was decided to readmit her to hospital.

After admission she complained of localized pain and tenderness over the right lobe of the liver, which, however, did not appear to be enlarged. There was no abdominal distension and the spleen was normal; cholecystitis was suspected.

On February 8th I again operated, using Kocher's incision, and on opening the peritoneum came straight on to a single localized abscess in the liver substance, the size of a golf-ball. There were dense adhesions between the border of the liver and the stomach and transverse colon. There was no sign of any trouble in the

The pus having been evacuated, a rubber drainage tube and gauze packing were inserted, and the wound was closed. The patient made an uninterrupted recovery and left hospital, feeling quite well, on March 7th.

WILLIAM GEORGE, M.B., Ch.B.,  
Honorary Surgeon, Royal Lancaster Infirmary.

## Reports of Societies.

### PORTAL CIRRHOSIS.

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland on March 16th, the president, Dr. T. T. O'Farrell, in the chair, Dr. V. M. Smyke read notes on a case of portal cirrhosis, and Dr. J. Laird demonstrated the specimens.

A woman, aged 56, was admitted to hospital in August, 1927, complaining of weakness and jaundice. She had been operated on two years previously for abdominal pain, and a small piece of liver had been removed for examination, the diagnosis being portal cirrhosis. The jaundice had commenced in the previous February. On admission the patient was rather deeply jaundiced and wasted; the hepatic facies was absent, and there was no history of vomiting. The liver extended two finger-breadths below the costal arch, and was slightly irregular on the surface; there was slight ascites. The urine contained bile, and the van den Bergh test gave a strong direct positive reaction, which was slightly delayed; the Wassermann reaction was negative. The spleen became slightly enlarged, and superficial distended veins appeared reaching from the groins to the umbilicus; the ascites remained slight, and the jaundice deepened, but the temperature remained normal except for occasional rises to 99° or 100° F. Death occurred in December. Clinically the case presented the appearance of the unclassified type of hepatic cirrhosis associated with enlarged spleen.

The liver was slightly atrophic, and when fixed weighed 40 oz. It had a well-developed "hobnail" appearance, and on section showed the typical appearance of a portal cirrhosis. Little fatty change was seen macroscopically, but the liver was deeply bile stained. Microscopical examination revealed the appearances commonly found in an advanced portal cirrhosis. In sections stained with Mallory's aniline blue the reticulo-endothelial cells were clearly seen, many of which contained bile. The spleen was slightly enlarged, and when fixed weighed 6 oz.

The President said that newly formed bile ducts were more commonly found in the other types of cirrhosis than in portal cirrhosis, and he wondered why in this case there had been bile retention; he had only met with it in one case, and that of genuine alcoholism. He suggested that in the present instance the pigment had been picked up by the Kupffer cells, and thought that it might be a disadvantage to remove the spleen in these cases.

Dr. A. R. Parsons said that this case seemed to combine the two types of cirrhosis—namely, the biliary and portal—and he regarded it as more like a case of the former. It made the differential diagnosis between these two types of cirrhosis still more difficult.

### Bacterial Agglutination.

Dr. J. W. Bigger read a paper on recent work on bacterial agglutination. He first dealt with the discovery of the phenomenon of agglutination and some of the early observations made on it. He explained Ehrlich's views on the relation of agglutinin to agglutigen, and pointed out the differences between major and minor agglutinogens as demonstrated by Castellani's absorption technique. He then reviewed Smith and Reagh's work on flagellar and somatic agglutinogens and agglutinins, and the discovery by Beyer and Reagh that flagellar agglutigen was thermolabile. Dr. Bigger's paper was chiefly concerned with the discovery by Weil and Felix of H and O types of culture, and the investigation by these workers, Sachs, Arkwright, Goyle, Bruce White, and others of the relation between the three types of culture (normal, smooth variant, and rough variant) and the three agglutinogens (H, O, and R). He showed that the normal type had two agglutinogens: H (heat labile and flocculating) and O (heat stable and granulating); the smooth variant only had O agglutigen, and the rough variant had a new heat-stable granulating agglutigen, R. Dr. Bigger next pointed out the importance of Andrews's discovery of the alternation of cultures of certain bacteria, particularly the *Salmonella bacilli*, as regards their H agglutinogens between the specific and group types. He concluded his paper with a consideration of Bruce White's work on the antigenic constituents of the members of the *Salmonella* group.

## Rebicus.

### HOWARD KELLY'S "GYNECOLOGY."

THE preface to the new work on *Gynecology*<sup>1</sup> by Professor HOWARD KELLY and a group of colleagues indicates that it is the swan song of the master whose name it bears. It begins, "The day's work is done, in the chiaroscuro of the evening I pen my last lines," and its closing words are, "My pleasant task is done; the shadows fall well aslant my page; it is almost time to draw the curtains and turn on the Great Light. To boon companions and travellers all—Vale!" A book that opens thus and bears the imprimatur of a revered name cannot be discussed as if it were one of the many medical treatises that come up for notice and soon pass out of mind. This contribution of Howard Kelly's is of the nature of a review of his experience in gynaecology by one who has served in the front line while it advanced from where he found it in the eighties to the much further forward position in which he leaves it forty years on. In his own words, "Not often does a man have a chance to write two books on the same subject at an interval of a generation, especially after such notable changes as the gynaecological field has witnessed."

If we were to try to give a general impression of this book we should describe it as an attempt to set out what has been done in the author's lifetime in gynaecology, particularly America's contribution and the position reached by the subject in the United States, with suggestions as to the direction which its further progress in that country is likely to take. Though it is not all from his own pen, this book is of him and his school, and out of its forty-nine chapters the master is responsible for eighteen, and no other single collaborator for more than three of the remainder; and throughout the work his influence is paramount. It covers the realm of gynaecology and even transgresses its frontiers, at any rate as marked out in this country, and is made up of a series of essays or tracts on the modern aspects of the subject, ranging from its anatomy, physiology, and pathology through its various therapeutic methods to its relations with endocrinology, psychiatry, and electrotherapy. Mention of some of the chapter headings will best illustrate their essay-like character. There is one on "Peritoneal tubal insufflation" (I. E. Rubin) and another on "Sacral anaesthesia"; one on "Adenomyoma," and another on "Endometriomata." "Protein therapy" and "Pneumoperitoneal roentgenography" have each a chapter, and two chapters of equal length and both profusely illustrated are given to hysterectomy—one by the abdominal and the other by the vaginal route. These examples will serve to show that space is not allotted to the subjects solely because of their importance in gynaecology, but rather because of recent work or recent tendencies that have called for special attention.

The series of four chapters devoted to prolapse and injuries of the pelvic floor may be singled out for the interesting review and beautiful illustrations they give of what surgery can do for these conditions. There is an anatomical chapter on the fascia and ligaments of the pelvis, another on laceration of the perineum, and two covering "cystocele and prolapsus" and "rectocele and enterocele." The Mayo operation for prolapsus is advocated, together with excision of the pouch of Douglas, in order to throw forwards the weight of the intestines in the erect position and relieve the rectum and posterior vaginal wall. There is an interesting chapter on menstruation, amenorrhoea, and dysmenorrhoea (Novak), in which the tendency to pay too much attention to anatomical defects is deplored, and a plea put forward that more consideration should be given to the study of physiology and the causes of disorders of function.

The whole book is of very great interest to us on this side of the Atlantic for the picture it gives of differences in practice and thought. Noteworthy features are the description of how a curetting may be done in the "office" and without anaesthesia, the greater emphasis that is laid on auxiliary examinations—blood investigations, basal

metabolism estimations, and suchlike—and even the much greater frequency in the United States of lumbosacral strain, which almost suggests that in that country there must be some inherent weakness of that pelvic joint in its womenkind. Even the variation in technical language is striking, when we read that dilatation and curettago is so common a procedure that "it is commonly docketed in our protocols simply under the initials 'D.' and 'C.'" In short, this work is certain of a welcome from Professor Howard Kelly's British colleagues, not only because it is his own review of the work of himself and his collaborators, but for the picture it gives of modern gynaecology as seen through the eyes of the best minds in the United States.

### PSYCHIATRY.

*Mental Disorders*,<sup>2</sup> by Dr. HUBERT J. NORMAN, is an eminently readable book. The author has departed from traditional procedure by relegating to a later portion of the book the psychological chapters which generally serve in most textbooks as an introduction to the study of mental disorders; but the arrangement is probably a sound one, for by according priority of position to the descriptions of the actual mental disorders the author ensures that the reader will approach the more theoretical parts with added interest.

This book is divided into two sections. In the first clinical aspects of psychiatry are dealt with, followed by an account of disorders associated with constitutional instability. Nothing of importance seems to have been omitted, even where the descriptions err on the side of undue brevity. The chapters on disorders associated with the psychoneuroses call for more comment. The classification of the psychoneuroses is a highly controversial subject, but by excluding Freud's classification altogether, Dr. Norman would seem to have carried his wish for avoidance of controversy a little too far. He seems out of sympathy with the Freudian interpretation of hysterical phenomena. He quotes Rosanoff as saying that the particular method of therapy is a matter of comparatively little importance in the cure of hysterical manifestations. This may be so, but the removal of the manifestations is not the same thing as radical cure of the disease. The amount of space devoted to a description of epilepsy and insanity seems insufficient; but on the whole these chapters contain much practical wisdom. Under the heading of symptomatic or associated disorders are grouped alcohol and drug addictions, mental disorders associated with bodily diseases and infections, and those associated with disease of the nervous system and with the epochs of life. The account given of these is satisfactory. In the chapter devoted to general paralysis we might perhaps have expected some reference to the view of Shaw Bolton.

Section Two is mainly concerned with a consideration of normal and abnormal psychology, and of the pathology of mental disorder. General treatment is also discussed, and the author has seen fit to include a chapter on "Clinical examples in life and literature." Legal considerations are fully stated. The grounds for establishing a defence under the McNaughten rules are given, and the main formula is accurately stated, but the alternative defence is not quite as Dr. Norman puts it before his readers. This, however, is a small matter. It is a book that may be safely recommended to the student and practitioner, and the author's easy style is not its least merit. Considerable expansion of the text would be advisable in any future editions.

### APPLIED BIOCHEMISTRY.

THE purpose of *Applied Biochemistry*,<sup>3</sup> by Professor MORSE of Philadelphia, is stated to be to weave the woof of biochemistry into the warp of medicine. It is said in the preface that each subject in the medical curriculum tends to grow steadily, and that, since the capacity of the medical

<sup>1</sup> *Gynecology*. By Howard A. Kelly, M.D., LL.D., and collaborators. New York and London: D. Appleton and Co. 1928. (Roy. 8vo, pp. xxxvi + 1043; 767 figures, 12 plates. 50s. net.)

<sup>2</sup> *Mental Disorders*. By Hubert J. Norman, M.B., Ch.B.Ed., D.P.M.Ed., and Glas. Edinburgh: E. and S. Livingstone. 1928. (Cr. 8vo, pp. xv + 463; 57 figures. 14s. net.)

<sup>3</sup> *Applied Biochemistry*. By Withrow Morse, Ph.D. Second edition, revised and reset with the co-operation of Joseph M. Looney, M.D. London: W. B. Saunders Company. 1927. (Med. 8vo, pp. 283; 270 figures. 32s. 6d. net.)

student is a more or less fixed quantity, it is necessary to make a careful selection so as to present to him or her only such portions of a special subject as are definitely related to medicine as a whole. This general aim is to be commended wholeheartedly, for biochemistry shows a tendency to develop as a specialized form of organic and physical chemistry and thus to become less and less intelligible to the medical student. Professor Morse, who in the preparation of this second edition has had the assistance of Dr. JOSEPH LOONEY, concentrated his attention on those problems of biochemistry which are of importance in the practice of medicine, and all who teach biochemistry to medical students will find the volume of great value and interest. Its perusal however, suggests certain doubts as to its suitability as a textbook of biochemistry for medical students themselves, at any rate for those who study in this country. The first obvious objection is to its size, for it contains nearly one thousand pages. This is due in part to the fact that directions for practical work are included in the body of the book, where details of some hundreds of exercises are given. In the second place, biochemistry has been interpreted in a wide sense, for the first hundred pages deal chiefly with physical chemistry. Hence the volume is considerably larger than is required by the ordinary medical student in this country who is studying biochemistry.

The book is profusely illustrated; the illustrations vary in value, for some are of quite simple chemical apparatus. A series of portraits of the leaders of biochemistry in America form an interesting feature of the book, but a somewhat curious effect is produced in places by the alternation of these portraits with illustrations of individuals suffering from various forms of deficiency disease. The general impression obtained from reading the book is that it is distinctly difficult to follow the main lines of description, partly because the text is broken up by descriptions of exercises and partly because the range of subjects dealt with has forced the authors to deal briefly with certain difficult points. This last feature is especially marked in the portion devoted to physical chemistry.

#### MALIGNANT FEVERS IN CHILDREN.

It is well known that side by side with mild or severe forms of various acute specific fevers there are malignant types which are terrible in their fatality, and yet give little or no *post-mortem* evidence as to how they differ from the ordinary forms of such diseases. Professor V. HUTINEL has collected a vast amount of clinical and pathological investigation in a volume devoted to the malignant syndrome in diseases of childhood,<sup>4</sup> in which he endeavours to deal with some of the problems of these curious maladies. It is especially in young children in hospitals that these malignant forms develop in the course of such generalized diseases as typhoid fever, scarlet fever, diphtheria, or in localized infections such as bronchitis, enterocolitis, or eczema. The clinical manifestations of "malignancy" appear to be various erythematous eruptions, vomiting, profound nervous depression with signs of circulatory disturbance, subnormal temperature, and death in coma. At necropsy the blood is found to be dark and thick, various organs are in a state of congestion with blood-stained effusions and fatty infiltration, but practically nothing else is found to correspond with the curious clinical condition. Professor Hutinel deals in some detail with the "malignant syndrome" as it appears in typhoid and scarlet fever, and then in a particularly good section he sums up his pathological and clinical experiences. He thinks that the phenomenon of anaphylaxis plays a part in many cases, and that streptococcal infection in a "sensitized" patient may explain some of the malignant forms. In a final section the hygienic measures necessary in a children's hospital to prevent the onset of the "malignant syndrome" are well discussed, since this is the only way in which such a fatal malady can be attacked. Professor Hutinel is well known as an exceptionally astute

observer, and these 300 pages of careful observations and cautious generalizations might well serve as a model for monographs of this type.

#### BLOOD GROUP DETERMINATION.

A SMALL monograph by Dr. SCHIFF<sup>5</sup> on the technique of blood group determination gives in a most concise and businesslike manner all the facts that are known about blood groups, with clear instructions for their investigation. Blood grouping is now fully recognized to possess great importance in relation not only to the therapeutics of blood transfusion, but also to anthropology and medico-legal work. There was need for a book such as this, in which the knowledge scattered in numerous periodicals is gathered together and made accessible. We are glad to note that Dr. Schiff does not regard as of much clinical importance the bogies that have been raised from time to time in the shape of groups additional to the usual four. For clinical purposes he recommends a relatively simple and rapid method of group determination. More elaborate methods are described for researchers and for medico-legal purposes; even the investigation of dried blood is included. The text includes a number of diagrams, some in colours. We can strongly recommend the work to those who are interested.

#### NOTES ON BOOKS.

PROFESSOR CH. ACHARD has again collected his clinical lectures at the Hôpital Beaujon for a third volume,<sup>6</sup> and the twenty articles which this book contains cover a wide range of subjects. Two lectures are devoted to pernicious anaemia, and some of the cases described have been carefully chosen to show how difficult the diagnosis may be in this disease, and how cautiously results must be estimated. A very instructive lecture is on the development of tuberculosis in the lungs of men who had been gassed in the war. Whereas in the early days after the war phthisis was rare as a sequel to gassing, it is now becoming increasingly common. Hodgkin's disease is well discussed, especially from the pathological point of view, under the name of malignant granulomatosis. The last lecture in the present series, however, is undoubtedly the best; it is entitled "Pharmaceutical specialties." Professor Achard carefully weighs up the advantages and disadvantages of what are called in this country "proprietary preparations," and he states deliberately that the harm they do outweighs the good. The volume contains some very good radiograms and other illustrations; it is well produced in the well-known "paper cover" style at a very moderate price.

*Les Bases Physiques de la Radiothérapie*<sup>7</sup> (the physics of radiotherapy), by JEAN DUBOST, is one of a series of short treatises on electrotherapeutics and allied subjects which are in course of publication under the direction of Dr. Duverné. It deals with x rays only, and stress is laid upon the point that, whilst superficial x-ray therapy is comparatively simple, deep x-ray therapy is dangerous, and especially so unless the qualified radiologist who directs it is well up in the scientific side of radiotherapy. The matter it contains is divided up into six chapters. After introducing his subject in a first chapter of generalities, the author continues with chapters on the production and the absorption of x rays. Filters and filtration are next considered, and, following a chapter on transformers, coils, and radiometry, and other methods of measuring the quantity of rays, the author concludes by contrasting superficial, deep, and semi-deep radiotherapy. It should be noted that the subject is approached entirely from the physicist's point of view.

The work on *Hypotension*<sup>8</sup> by Dr. ALFRED FRIEDLANDER, professor of medicine at the University of Cincinnati College of Medicine, forms volume xiii of Medicine Monographs, and is a reproduction in book form of the paper which appeared in the May issue of *Medicine*, and was abstracted in our *Epitome* of October 1st, 1927 (para. 281).

# British Medical Journal.

SATURDAY, APRIL 14TH, 1928.

## THE FRACTURE PROBLEM.

THE discussion on the treatment of recent fractures by operation, which was held in the Section of Orthopaedics of the Royal Society of Medicine on April 3rd, once more ventilated a much vexed question. It was opened by Dr. Charles Scudder of Boston, Massachusetts, who is one of the leading authorities, if not the very first authority, on the subject of fractures in general. The treatment of fractures has always been an important part of surgery, although of late years it may have lost its attraction for some surgeons, whose interests have become locked up in the treatment of disease in the cavities of the body, and especially in the abdomen. It is to-day of greater importance than ever, and of growing importance, for, as we said when reviewing the last edition of Dr. Scudder's book on fractures,<sup>1</sup> the number of accidents involving injury to the skeleton has increased to an appalling total with the rapid increase of motor traffic, while such accidents occur, not, as in former times, mainly in the neighbourhood of cities and well-equipped hospitals, but in all parts of the country, wherever there are roads and motor cars to run upon them.

Dr. Scudder took a wide view of his subject, as, indeed, his experience and his scientific training impelled him to do. On the whole, he was inclined to favour a more frequent resort to open operation and adjustment of simple fractures than has lately found favour in this country, although he frankly stated that there were certain types of recent fracture, such as those of the neck of the thigh bone, which he and his colleagues in the fracture service of the Massachusetts General Hospital did not at present consider suitable for operation. He was inclined to place exact anatomical correction of fractures first, and to esteem it as the best means of ensuring good functional results. Sir Robert Jones, who followed him in the discussion, was in favour of less radical measures, and set a good functional result as the ideal to be aimed at, no matter what the anatomical end-result might be. As one of the advantages of open operation and metallic fixation Dr. Scudder claims quicker healing and a shorter period of fixation. Mr. Hey Groves, Mr. Fairbank, and some other speakers took a contrary view, maintaining that in their experience repair was delayed when plates or bands or screws were used. Dr. Scudder's eloquent plea in favour of living bone tissue and its right to be treated as a sensitive growing organ of physiological importance, and not as the mere material of a mechanical framework, is, we think, better respected by the non-operative than by the plating method of treatment.

The differences of opinion among some of the most skilful and most experienced surgeons as to the best method of treating any particular type of fracture are due not so much to personal idiosyncrasy as to lack of exact knowledge of results. If it could be shown authoritatively that a certain method was unquestionably the best, all surgeons would follow that method to the exclusion of others. In the United States and Canada the Fracture Committee of the American Medical

Association and the American College of Surgeons has laudably attempted to arrive at some such conclusion, but, as Dr. Scudder told his audience on April 3rd, their efforts were to a great extent frustrated by the imperfection of the records, even those of hospitals classed as belonging to grade A. Until a similar inquiry has been made in this country it is not possible to state whether our records are more satisfactory or not. Dr. Scudder's standard for a fracture specialist is a high one, and no doubt it is reached not only by himself, but by his colleagues of the fracture service of the Massachusetts General Hospital. He rightly postulated for such a surgeon wide and deep scientific knowledge and a delicacy of technique not less than that of an abdominal surgeon. He recognizes, as we all do, that the first treatment must as a rule be given by a general practitioner, and that as the quality of that treatment has a most important bearing on the later progress of the case, it must be appropriate and skilful. The definitive treatment should be undertaken by skilled specialists, who would use the best means available, whether these included open operation, plating, or more conservative methods. Assuming an adequate supply of skilled general practitioners able to give proper early treatment, is the supply of specialists and surgical teams adequate? We agree with Mr. Cochrane that it is of no use issuing instructions if the skilled staff and organization which is necessary to carry them out does not exist. In a recent annotation on some aspects of the matter<sup>2</sup> we once more directed attention to some of the crying needs of fracture treatment in our hospitals.

It is to be hoped that the important discussion that took place last week before the influential gathering which filled the Barnes Hall of the Royal Society of Medicine will bear fruit. Meanwhile, it might surely be wise to take a hint from our American colleagues, and try to ascertain the results of different methods of treatment as practised throughout the British Empire. We all know that good results are achieved by extension methods, by massage and manipulation, by followers of the teaching of Lucas-Championnière, by open reposition, and by plating. Mr. J. W. Dowden of Edinburgh has recorded good functional results from a non-restrictive method which encourages movement, even in compound fractures, and makes light of deformity. We want to be able to avail ourselves of the merits of this and every system, while rejecting their defects. To enable this to be done, we need a set of criteria by which the surgeon may judge what method to employ in any given case, and when to substitute one means for another. Above all, there is need of surgeons who are not only well skilled in the surgery of fractures, but keenly interested in this important work.

## DYSPHAGIA ASSOCIATED WITH ANAEMIA.

PROBLEMS in the domain of practical medicine are seldom capable of rapid and complete solution. Workers, necessarily limited to sections of so vast a field, cannot always see things as they really are and estimate their intrinsic worth, and progress may only be possible by enlarging their horizon. From this point of view the recent discussion in the *British Medical Journal* on the subject of dysphagia associated with anaemia is welcome as evidence of a renewed interest in its wider bearings. Since Brown Kelly and Paterson in separate communications drew attention to it in 1919 this clinical type of dysphagia has hardly

<sup>1</sup> *British Medical Journal*, March 10th, 1928, p. 396.

<sup>2</sup> *British Medical Journal*, January 21st, 1928, p. 107.

received the notice it deserves, and its discussion is still mainly confined to laryngologists. It may therefore be opportune to give a short survey of some aspects of the problem.

Its essential feature—a gradually increasing inability to swallow, occurring only in women—generally brings the patient under observation about middle age, when she is no longer able to swallow more than liquid food. Little is known of its early phase, as the patient is rarely seen on the threshold of her difficulty, which is usually of long standing, and upon this point further observations might well be forthcoming. Once established, though it may vary and be improved by passage of a bougie, it is rarely absent. The patient's general state long remains good, and, learning to model her life by the limitation of "a small swallow," she is able to carry on domestic duties until a late stage. She is frequently edentulous. In most cases glossitis is present, and the atrophic change in the mucosa, extending to the buccal cavity, pharynx, hypopharynx, and even to the upper part of the oesophagus, is limited to the food tract. Anaemia is a prominent symptom. Endoscopic examination reveals a characteristic departure from the normal. The rounded mucous folds of the deepest part of the hypopharynx, which permit an oesophagoscope to be passed with ease, are now thin tense bands that change direction or come into prominence as the tube seeks the opening. This is small and difficult to find, because it is often minute, even pinhole or a narrow slit. Once entered, however, it can be dilated to take a large-sized tube. The rigidity of the parts, retained even in deep anaesthesia, and the thinness of a mucosa very liable to crack, demand care to avoid making a false passage.

Interpretation of these changes has called forth considerable discussion. Brown Kelly and Paterson regard them as primarily due to pharyngo-oesophageal spasm, though it cannot be gainsaid that the altered mucosa may to some extent emphasize the difficulty. William Hill, who has done much to clarify our ideas of the anatomical relations of the lower pharynx and oesophagus, is unable to view it as an active contraction. The dysphagia he looks upon as pharyngeal, of the nature of a muscular paresis coexisting with lowered sensibility of the mucosa and an impaired reflex. This may well be the explanation in cases which permit the endoscope to enter without much effort, and perhaps belong to a different category. The recent suggestion of Hurst, who sees in it unrelaxation—achalasia—of the lowest part of the inferior constrictor, brings it into harmony with his well-known views on the nature of "cardiospasm." But it would be hard to maintain that spasm was at least not coexistent. The difficulty in such patients of passing a bougie, and the striking improvement often seen when it is successful, have a significance of their own. Dr. Hurst is, however, well able to argue his case for achalasia of the cardia as against cardiospasm, and the discussion in our correspondence column appears to have narrowed itself now to a debate on this point between himself and Dr. Brown Kelly.

Hitherto the type of anaemia has been regarded as in the main a diminution of the haemoglobin content, perhaps to be explained by the enforced restriction of food. Cameron, reporting lately on a group of Brown Kelly's cases, confirms this. Looking at it from the point of view of the physician, Hurst has drawn attention to a paper by Plummer and Vinson, reporting 69 cases of functional dysphagia, of which 37 had secondary anaemia and 12 splenomegaly. The patients recovered on the administration of iron and the passage

of a bougie. There is no mention of glossitis. Careful examinations in this country had failed to note enlarged spleen, but Hurst himself has recently observed four cases. Further investigation of this aspect of the problem is clearly desirable.

Finally, it is worth bearing in mind that malignant disease shows a striking tendency in women to involve the oral pharynx and hypopharynx, the area of the atrophic change in the mucosa, and this termination is no unusual event in the cases under consideration. In men, on the other hand, in whom this dysphagia is never seen, cancer is more common in the tongue and lower oesophagus. This striking contrast in sex incidence suggests the taking of a wider view of the whole problem. We are far from having heard the last word, and there is clearly a need here which begs for close co-operation between the laryngologist and the physician.

#### THE PULPLESS TOOTH.

In the *Journal* of March 31st (p. 548) we gave an account of a discussion on the pulpless tooth at a joint meeting of the Sections of Odontology, Electro-Therapeutics, and Pathology of the Royal Society of Medicine; in an earlier issue (January 28th, p. 135) we reported a paper by Mr. Arthur Bulleid on apical infection, read before the Odontological Section of the same Society; and last week (p. 589) we published a paper by Mr. A. P. Bertwistle dealing with the same subject. Perusal of these communications shows that the pulpless tooth has no real friends. The doctor asks, "What damage is it doing?" while the dentist seeks on the one hand a means of sterilization, and on the other hand a reliable clinical answer to the question, "Is it infecting the patient?" No one disputes its power for evil. Mr. Bertwistle gives an answer to the doctor's query in a series of interesting cases which are well worthy of study, and quotes Sir William Willcox to show how prevalent are "rheumatic" diseases due to pulpless teeth. There is a general agreement that the infecting agent is a streptococcus, but while the present confusion of nomenclature persists it is impossible to know whether *Streptococcus salivarius* of one author is to be regarded as identical with *Streptococcus longus* (non-haemolytic), or with *Streptococcus longus* var. *viridans* of another, or whether there is a definite differentiation. This is a point we hope the Streptococcus Committee will soon clear up. Mr. Bertwistle gives "tenderness on eating" as the most trustworthy clinical sign that a pulpless tooth is infecting the patient; but the experience of the dentist is that tenderness to pressure on the gum over the apex of the root is an even more delicate test than discomfort on biting or percussion, while there are cases in which not even this tenderness can be elicited. Radiography has not provided a full answer; no lesion may be demonstrable by x rays, and yet the tooth may be infecting the patient. There is, indeed, considerable controversy as to the meaning of the x-ray appearances observed round the apices of dead teeth. A radiolucent periapical area fading away through a less radiolucent area to normal bone has hitherto been regarded as a sign of open infection, and as showing a failure of local resistance. An area of sclerosed bone surrounding a radiolucent area or immediately around the pulpless tooth has been regarded as at least a better bar to infection and as showing some power of local resistance. These views are consonant with the generally accepted pathology of bone. They have, however, been vigorously challenged by Weston Price. This author concludes, as the result of both clinical and laboratory investigation into a large number of cases, that exactly the reverse is the case: the sclerotic area betokens danger, the fading radiolucent area betokens

active resistance. However this may be, Bulleid found germs in every granuloma he examined (the radiolucent periapical area is occupied either by a granuloma or by pus), and the net result is that any divergence from the normal shown by x rays must be considered as a danger signal; and even normal x-ray appearances are not a guarantee of safety. On the question of the sterilization of the pulpless tooth, the combined discussion at the Royal Society of Medicine is very illuminating. Pulpless teeth are divided into those already dead and infected, and those whose pulps the dentist kills, and which, *ex hypothesi*, are sterile *qua* the root canal. The first class may be sterilized, more or less, mechanically and by the use of germicides; the second class may be brought to a successful issue by aseptic treatment throughout; but so insistent are the dangers of infection in the work of dental surgery that no speaker was found to claim permanent success for either class. Pulpless teeth must always remain suspect. In the course of this discussion Dr. Murray Levick, for the Section of Electro-Therapeutics, vividly described the danger of applying ultra-violet rays to the mucous membrane, but reported good results from treatment of the gums by red rays. Ionic medication was referred to by one speaker only—Mr. Morphy (Section of Odontology). Whether, or under what conditions, an electric current can be passed through a devitalized tooth-root is a question which might well occupy the Section of Electro-Therapeutics, and many dentists, we understand, had hoped that an answer would be forthcoming in this joint discussion.

#### A SWEDISH SOCIAL EXPERIMENT IN TUBERCULOSIS.

WHILE most tuberculosis workers know something about the Framingham demonstration in the United States of America, it is probable that few are familiar with a somewhat similar experiment which was started in Sweden in 1904. In that year the then secretary of the Swedish National Association against Tuberculosis, Dr. B. Buhre, drew up a programme, according to part of which some poor parish, situated in a remote area with bad communications, inhabited by a comparatively stationary population, and afflicted with tuberculosis, was to be chosen for demonstrating the effects of a carefully organized campaign against this disease. A cottage hospital was to be provided, with accommodation not only for tuberculous patients, but also, in a separate part of the building, for children who were still quite healthy and who had been removed from tuberculous surroundings in their own homes. A tuberculosis officer, assisted by a special staff of nurses, was to live in this parish, devoting his time to examining as many as possible of the inhabitants, and to helping them to lead healthier lives and to rear a new generation which should be less afflicted by this disease. An account of this experiment has lately been published in *Acta Tuberculosea Scandinavica*<sup>1</sup> by Dr. G. Neander, the present secretary-general of the Swedish National Association against Tuberculosis, and for many years resident tuberculosis officer in the parish in question. This parish is in the district of Neder-Luleå, in the county of Norrbotten, in the extreme north of Sweden. A manifesto was issued which stated the objects of the experiment, and the inhabitants of the parish were invited to sign it. The first tuberculosis officer was appointed in January, 1906, and his wholesale examination of the inhabitants showed that 10.75 per cent. of the 1,498 persons examined were suffering from undoubted pulmonary tuberculosis, and 5.9 per cent. from suspicious signs of this disease. When, in March, 1908, Dr. Neander was appointed as

tuberculosis officer, he proceeded to examine 1,652 of the 1,860 inhabitants of the parish, finding undoubted pulmonary tuberculosis in 10.23 per cent., and suspicious signs of this disease in 4 per cent. Several of these suspects being found to be definitely tuberculous, the proportion of cases of undoubted pulmonary tuberculosis amounted to 12 per cent. of the total population examined. In an additional 2 per cent. there were signs of surgical tuberculosis. While space does not permit of even a brief reference to all the activities of this tuberculosis experiment or demonstration, it should be noted that an inquiry was simultaneously conducted into the incidence of bovine tuberculosis in the same parish, and, though there were many opportunities for infection of the cattle by tuberculous attendants, none of the 263 animals, belonging to forty-two herds, gave a positive reaction to tuberculin. It would therefore seem that the tuberculosis from which the inhabitants suffered was of human origin. In November, 1926, Dr. Neander again carried out a general inspection of the entire population, 1,834 persons being examined. The number of cases of pulmonary tuberculosis found in 1926 corresponded to 8 per cent. of the total population, as compared with 12 per cent. in 1908. With the addition of cases of surgical tuberculosis the total incidence of tuberculosis was 9.5 per cent. in 1926, as compared with 14 per cent. in 1908. A comparison of the tuberculosis death rate for the two five-year periods 1911-15 and 1921-25 showed that in the whole county of Norrbotten there was a decrease of 11 per cent., in the whole of the district of Neder-Luleå it was only 0.5 per cent., whereas in the experimental area it was 28 per cent. Dr. Neander disclaims any intention to assert categorically that this decrease was the result of the demonstration, but he suggests that there are good reasons for presuming that it was the principal cause of this decrease; and it was achieved at comparatively little cost.

#### THE PRODUCTION OF ALKALOIDS.

DR. T. A. HENRY,<sup>1</sup> in a recent address to the Society of Economic Biologists, pointed to some curious unsolved problems regarding alkaloids. The importance of these substances to mankind is obvious, for as a people we consume them by the ton in tea, coffee, and tobacco; they constitute our most valuable medicines, and their abuse in the form of morphine and cocaine is a serious social problem. The first alkaloid to be discovered—namely, morphine—was isolated more than a hundred years ago, and since then organic chemists have worked continuously at the isolation and analysis of these substances. Consequently a large amount of exact knowledge has been acquired regarding alkaloids. Hundreds have been discovered and the chemical constitution of the great majority has been determined, and finally the synthesis of a considerable number has been achieved. Nevertheless, no natural alkaloid has so far been replaced commercially by its synthetic equivalent, and therefore the organic chemist cannot yet claim to rival the plants in the efficiency of his manufacture of these chemicals. Moreover, the synthesis of the most important medicinal alkaloids, such as morphine, quinine, and cocaine, has not yet been achieved, nor has any synthetic product been discovered which is a full therapeutic equivalent of any of these drugs. Mankind is therefore still dependent on plants for its supply of alkaloids, and yet, strangely enough, we have no idea why the plant makes these valuable substances. Practically nothing is known regarding the part they play in the physiology of the plant. Dr. Henry recalled three explanations that have been advanced to account for the occurrence of alkaloids—namely: (1) that they are produced as protective agents; (2) that they are plastic products destined

<sup>1</sup> The "Halsan" Institute in Norrbotten. An Experiment on the Lines of Social Hygiene in the Far North of Sweden, organized by the Swedish National Association against Tuberculosis, together with a Study on the Dissemination of Tuberculosis in Sweden. By Gustaf Neander, M.D. From the *Acta Tuberculosea Scandinavica*. Translated by Greville Grove. Copenhagen: Levin and Munksgaard. 1928. (6½ x 10, pp. 127; 20 figures.)

<sup>1</sup> T. A. Henry: *The Annals of Applied Biology*, xiv, 532, 1927.

for further use by the plant; (3) that they are waste products. He showed that the first view was untenable, and that the balance of evidence was in favour of alkaloids being waste products. He mentioned in support of this view the fact that alkaloids are not as a rule found in quantity in seats of active metabolism, such as the leaves, except in short-lived plants, where other means of storage are not available; but that in perennial plants the usual source of alkaloids is the bark or the seed coats. If this view is indeed correct, and alkaloids are only accidental waste products stored by plants in any place where they are conveniently out of the way, then their intense and specific pharmacological actions become more mysterious than ever. The attempts to produce synthetic substitutes for natural alkaloids have been surprisingly unsuccessful. For example, organic chemists and pharmacologists all over the world have tried to obtain substitutes for cocaine. Many valuable drugs have been discovered, but none of those produced is a full substitute for cocaine as a local anaesthetic. The suggestion that these alkaloids, so hard to imitate, are merely accidental waste products tinges our disappointments with humiliation.

#### POSSIBLE DANGERS OF COD-LIVER OIL.

THE administration of emulsions of cod-liver oil to even quite young babies is a very widespread practice at the present day almost throughout the Western world. At some institutions and in some welfare centres almost every patient receives certain vitamins in this form, and it is generally assumed that even if definite deficiency disease is absent the employment of cod-liver oil is certainly prophylactic and can do no harm. During the past few years certain investigators have called attention to the possible dangers of cod-liver oil administration, and in the Scandinavian medical journal *Acta Paediatrica* a controversy has been in progress since 1926 between E. Agduhr and A. Höjer on this subject. In a recent issue<sup>1</sup> the former describes his latest work and replies to the criticisms of Höjer. Agduhr has shown that in animals on a basal diet cod-liver oil may produce a poisonous by-effect by producing changes in the musculature of the heart. Höjer maintained that these changes were due to overdosage with vitamin A only when B and C were deficient in the basal diet. Agduhr, in reply, brings forward evidence to show that vitamins B and C were well supplied in his experimental basal diet, and cites also some new work on rabbits in which, with a basal diet of hay, oats, and turnips, enriched by marmite and lemon juice, morphological and electro-cardiographic changes in the heart have been produced by doses of 1 to 5 c.cm. of cod-liver oil per kilo body weight. He considers Höjer's further criticisms in some detail, and concludes that the changes produced by overdosage with cod-liver oil have nothing to do with deficiency of the B and C vitamins, although the work is complicated by the fact that animals differ greatly in their susceptibility to the poisonous effects of cod-liver oil, and also because some animals show a greater resistance to these effects during the summer than during the winter months. Agduhr deals next with the problem of whether vitamin A is the cause of these poisonous effects on the organism. He quotes work by Takahashi in which animals were killed by poisonous doses of biosterin. Although the pathological effects were not completely identical with regard to fibrinous changes in the heart and fatty degeneration in the liver produced by overdosage with cod-liver oil, yet it is considered that the difference in the injuries observed is no greater than can be explained by the considerably more concentrated doses of poison given in Takahashi's experiments. Agduhr believes, therefore, that the vitamins of the oil, together possibly with other con-

stituents, may produce undesirable effects when taken in large doses over a long period. If the doses used for animals in the experiments are transferred directly on a basis of body weight to the human subject, very large amounts of cod-liver oil would have to be given to produce ill effects in babies. But, as Agduhr rightly points out, in the dog, for example, the actual maximum doses of drugs are often higher than in the human subject, and he quotes one recent case of a premature infant which died when 4 months old, in which the characteristic changes were present in the heart following a daily administration of two teaspoonfuls of cod-liver oil. This is a large dose at this age, but it is one which is not infrequently given by enthusiasts, and, in view of modern concentrated preparations of the vitamins of this oil, it seems necessary to call attention to the possibilities of harm from overdosage. The medical practitioner is very likely to receive his information on these vitamins from manufacturers' pamphlets, where the work of such investigators as Agduhr is not likely to receive mention. The subject is of sufficient importance to warrant further investigation.

#### WORLD POPULATION PROBLEMS.

MOST of the pressing social and economic questions of to-day are outgrowths from the central problem of population. In the sphere of domestic affairs housing and public health are notable examples, arising as they do from the urbanization which has more and more characterized our history for the past 150 years. In international affairs the old conception of foreign policy as being primarily concerned with prestige and territorial sovereignty no longer obscures the fact that commercial treaties, tariff barriers, and migration policies are the things that matter. Standards of living, adequacy of employment, social services, and public health are the criteria by which a nation is now judged, rather than the extent of its realms or the magnificence of its ruler. War is threatened or waged not for the dignity of a king, but to secure outlets for the energy of a people. The Disraelian division of England into "two worlds" may be applied to the whole globe. There are rich countries which have an adequate population and a superfluity of material wealth. There are poor countries in which, with over-population, hunger is a normal circumstance and famine an ever-present danger; in them housing is poor, the public health organization insufficient or absent, and disease widespread. There is no need to emphasize the dangerous instability that must arise when such sharply contrasting circumstances exist in a world in which improved communications, the free exchange of knowledge and news, and closer trade relations are making isolationist national policies impossible. There is at least the appearance of inequity, and this becomes a peril when, as in these present times, the "have nots" are conscious of the sharp differences between their position and that of the "haves." International problems of this nature are unfortunately often left to the frothy sentimentalists or to the hard-headed "practical" people who over-simplify the problem, confine themselves to the more obvious facts, and shirk the study of causes. Something has, however, been done to provide a rational scientific basis for discussion, and a valuable collection of material for study is now available in the *Proceedings of the World Population Conference*,<sup>1</sup> which contains reports of papers read at Geneva last summer. Sir Bernard Mallet, formerly Registrar-General for England and Wales, presided, and the conference included representatives (in the unofficial sense) of every important country and almost every branch of science. One of the aims of the conference was to bring the sociologists more into touch with the biologists, thus

<sup>1</sup> *Acta Paediatrica*, 1928, vol. vii, fasc. 3-4, p. 289.

<sup>1</sup> *Proceedings of the World Population Conference*. Edited by Mrs. Margaret Sanger. London: E. Arnold and Co. 1927. (Med. 8vo, pp. 383; 1 plate. 20s. net.)

broadening the basis of discussion and action. The immediate result was the setting up of a permanent union for the study of population, and for the work of organization this volume may well serve as a starting point. Among the British contributors to the proceedings at Geneva were Professor A. M. Carr-Saunders, whose subject was differential fertility; Dr. F. A. E. Crew, who discussed fertility and sterility in relation to population; Professor J. W. Gregory, who dealt in a supplementary paper with the principles of migration restriction; and Mr. E. J. Lidbetter, whose paper on heredity, disease, and pauperism recorded the results of some interesting research work in East London. Professor Raymond Pearl, of Johns Hopkins Hospital, U.S.A., contributed a tentative summary of the relations between birth rates, death rates, and the density of population, which he believed was applicable to populations of organisms ranging from bacteria to man. On the general side a notable address was that given by M. Albert Thomas on the problem of international migration and its control—a problem which has been brought into prominence by the restrictive policy pursued by the United States since 1920. With the subject-matter ranging from biology to international politics it would be idle to expect exhaustive treatment of any topic within the compass of one volume, but the various papers and discussions reported should at least provide a suggestive book of reference for those who wish to gain a broad conception of the whole problem. It will have served its main purpose, no doubt, if it inaugurates an attack from as many angles as possible on the population question.

#### B.M.A. SCHOLARSHIPS AND GRANTS.

THE Council of the British Medical Association is prepared to receive applications for an Ernest Hart Memorial Scholarship, of the value of £200 per annum, and three Research Scholarships, each of the value of £150 per annum, all being open to candidates capable of undertaking research in any subject (including State medicine) relating to the causation, prevention, or treatment of disease. Each scholarship is tenable for one year from October 1st, 1928, but the period may be extended by not more than two additional terms. Provided it does not interfere with his research work a scholar may at the same time hold a junior appointment at a university, medical school, or hospital. Applications for grants in aid of research of a similar scope will also be considered. Preference will be given, other things being equal, to members of the medical profession and to applicants who propose to deal with problems directly related to practical medicine. Forms of application, which must be returned not later than Saturday, June 2nd, 1928, may be obtained, with other particulars, from the Medical Secretary of the Association, B.M.A. House, Tavistock Square, W.C.1.

#### BRITISH EMPIRE CANCER CAMPAIGN.

THE International Convention of the British Empire Cancer Campaign will be held in London from July 17th to the 20th, under the presidency of Sir John Bland-Sutton. The Convention will comprise six sections: Professor Lazarus-Barlow will preside over the section of pathology, and Sir Thomas Horder over that of diagnosis; the chairmen of the sections of medicine and surgery will be, respectively, Sir William Hale-White and Sir Charles Gordon-Watson; the section of radiology will have for its chairman Professor Sidney Russ, and that of statistics and public health will be presided over by Dr. F. E. Fremantle, M.P. General discussions are being arranged on the relative values of surgery and radiation in the treatment of cancer of the cervix uteri, rectum, buccal cavity, and breast; the etiology of cancer; and chemotherapy, with special reference to lead. The subjects for sectional discussion will

include the biological effects of radium and x rays; occupational cancer; the relations between clinical malignancy, histological characters, and response to treatment; diagnostic methods; the geographical and racial prevalence of cancer; the effects of radium and x rays on the blood, vascular, and lymphatic systems, with special reference to the treatment of malignant growths; and public action in regard to cancer. It is hoped to arrange for operations and demonstrations at various centres each afternoon during the meeting of the Convention. Inquiries may be addressed to Mr. Cecil Rowntree, chairman of the executive subcommittee, 9, Upper Brook Street, W.1.

THE KING has appointed Mr. Wilfred Trotter, M.S., F.R.C.S., to be Honorary Surgeon to His Majesty in the room of Sir Hugh Mallinson Rigby, K.C.V.O., whose appointment as Serjeant-Surgeon was announced in our issue of March 17th (p. 460). The King has also appointed Mr. T. P. Dunhill, C.M.G., to be Surgeon to His Majesty's Household in succession to Sir Hugh Rigby.

SIR MALCOLM WATSON, M.D., has been awarded the Founder's Medal for 1928 of the Asiatic Society of Bengal, in recognition of his antimalarial work in Malaya.

## Scotland.

### Medical Appointments to the King's Household in Scotland.

As announced briefly last week, four new medical appointments have been made to the King's Household in Scotland. Dr. Ashley W. Mackintosh, who has been appointed honorary physician, has been regius professor of medicine in the University of Aberdeen since 1912; Professor John Marnoch, C.V.O., and Professor John Fraser, M.D., who become honorary surgeons, hold respectively the regius chair of surgery in the University of Aberdeen and the regius chair of clinical surgery in the University of Edinburgh; while Dr. Arthur H. Sinclair, who has been appointed honorary surgeon oculist, is lecturer on diseases of the eye in Edinburgh University.

### Retirement of Professor Gulland from Edinburgh Royal Infirmary.

At a meeting of the board of managers of the Royal Infirmary of Edinburgh on April 2nd it was announced that Professor G. Lovell Gulland had retired from the Royal Infirmary as from March 31st. The managers passed a vote of thanks to him for his services to the institution, and appointed him an honorary consulting physician to the infirmary. The chairman said that Professor Gulland had graduated in 1886, and had acted as house-physician to the late Professor Sir Thomas Grainger Stewart. Six years later he had been elected an assistant physician, and after nineteen years of service in this capacity he became a physician with charge of wards. In 1915 he was elected to the chair of medicine in the University of Edinburgh, and he had continued to be an earnest and successful clinical worker, attaining a position as one of the leading authorities on diseases of the blood. His popularity as a teacher had been evidenced by the large number of students he attracted to his wards.

### Chairmanship of Scottish Board of Health.

The retirement of Mr. Ewan Macpherson from the chairmanship of the Scottish Board of Health is announced. He will be succeeded by Sir James Leishman, who was the first chairman of the National Health Insurance Commission for Scotland, and has been a member of the Scottish Board of Health since it was formed by the amalgamation of the Insurance Commission with the Local Government Board. Sir James Leishman is well known for his services to education. He was for several years a member of the Edinburgh School Board, and was convener of its Higher Education Committee when this committee took up the duty of developing continuation class work

in the city. In 1904 he was elected to the Edinburgh Town Council, and in 1909 he was appointed to the board of management of the College of Art. After 1910 he became treasurer of the City of Edinburgh, and held this post for several years. Since the introduction of the national health insurance scheme he has taken a very active part in its administration in Scotland.

#### Presentation to Dr. James Crockett.

Dr. James Crockett, who has retired from the post of medical superintendent of the Consumption Sanatorium of Scotland, Bridge of Weir, was on March 31st presented with a testimonial. In acknowledging the gift he said that tuberculosis, so far as Scotland was concerned, seemed to be a disappearing disease; he believed that in little more than a generation it would be a factor of relatively minor importance in the life of the nation, and would probably be as rare as typhus, leprosy, small-pox, or plague. Between 1912 and 1926 there had been a fall of 43 per cent. in the death rate from this disease. The climate of Scotland was often wrongly blamed for tuberculosis, but while in 1926 its death rate in Scotland had been 99 per 100,000, in Paris it was 301, in Madrid 293, in Manila 541, in Sofia 577, and in thirty Swiss cities 137. It was indeed somewhat difficult now to find a country where the death rate from this disease was lower than in Scotland. Other climates might be pleasanter, but few countries were healthier. With regard to the efficiency of treatment, in 1912 the Bridge of Weir Sanatorium had discharged 3 per cent. with the disease apparently arrested, 63 per cent. improved, while 34 per cent. were not improved or died. Compared with this, in 1926 40 per cent. of those discharged had the disease arrested, 34 per cent. were improved, and 26 per cent. were not improved or died. This might be due either to the fact that they were now dealing with a more hopeful type of the disease, or because the disease was changing its character and becoming more amenable to treatment. Tuberculosis was an index of social conditions, and when these were bad the death rate was high. Modern legislation had done more to bring about the fall in the death rate than anything contributed by medical discoveries. Legislative measures in this direction would prove investments with great capital appreciation.

## England and Wales.

#### Cancer Research by Medical Women.

At a meeting of the London Association of Medical Women's Federation on March 27th, at the House of the British Medical Association, with Miss Elizabeth Bolton, the president, in the chair, Miss M. Chadburn gave an account of the work undertaken by the Cancer Research Subcommittee since its formation in 1925, with special reference to radium treatment of uterine cancer, at the Royal Free Hospital, the South London Hospital for Women, the Elizabeth Garrett Anderson Hospital, and the New Sussex Hospital for Women, in co-operation with Dr. Hurdon. The need for concentrating the work for the most part in one centre was becoming more and more apparent. It had been estimated that £10,000 would suffice at first. Dr. Hurdon said that during the last few years radium had largely taken the place of surgery in the treatment of cancer occurring in accessible situations; dosage was now becoming standardized, and for the most part adequate doses were given. Unfortunately more than half of the patients presented themselves when the growth was already inoperable, usually six to nine months after symptoms had first been noticed. In the series of cases treated by the committee of the Women's Medical Federation only 15 per cent. were operable when first seen. A modification of the technique used by Heyman of Stockholm had been adopted, since on the whole his results over long periods seemed to be better than those of others. Many Continental clinics used this technique, though in France and Italy that of Regaud seemed to be more favoured. It was too early yet to make any claims for the final outcome of treatment in the cases under Dr. Hurdon's observation. Of 188 patients who started treatment between October, 1925, and March, 1928, there were 169 cases of

cancer of the cervix, 15 of cancer of the body, and 4 of cancer of the vagina or vulva. In March, 1928, 70 per cent. of these patients were still alive. Of those who were operable over 95 per cent. were living and were free from symptoms. Certain complications might occur after radium treatment, such as fistulae, rectal ulcer, or pain, tenesmus, and the passage of blood or mucus. These complications were happily rare; for example, fistulae attributable to radium had occurred in only two cases in the series under discussion. The following up of patients was most important; though it was very difficult to trace them, especially in London, only two had been lost sight of. Dr. Helen Chambers pointed out that the most suitable technique could only be determined after many years of trial, but the work of Professor S. Russ on experimental animals had been most helpful. He had inserted tubes of radium and then excised a piece of the tumour after varying intervals, testing the viability of the portion excised by transplanting it into another animal; in this way the range of effect, which was the most important factor, could be estimated. Dr. Chambers showed diagrams of the various methods used in different clinics, explaining that the method of inserting a tube into the cervix without placing other tubes in the vault of the vagina was ineffective. She emphasized the importance of distributing the tubes in view of the fact that the range of effect did not exceed half an inch. Soft rays had low penetrating power and caused local sloughing; hence the need for screening. The ideal aimed at was the disappearance of the growth with the minimum damage to healthy tissues; gamma rays appeared to be the most useful agent for this purpose. Professor Louise McLroy congratulated the association on the first piece of organized research undertaken by medical women as a group. She commented on the fact that patients in early stages often omitted to report their symptoms, which might be very slight—perhaps a little haemorrhage and no pain, even when the growth had reached the inoperable stage. For the last two years she had ceased to operate on cases of cancer of the cervix, and was using radium instead, with what appeared so far to be excellent results. It was important to disseminate the knowledge that non-operative treatment was available, since this might lead patients to seek advice earlier. Miss G. Dearnley said that the improvement in general health after radiotherapy was impressive. She had removed one uterus after treatment, and no trace of growth could be found even microscopically. Miss L. Martindale remarked that more beds were urgently required. It was often difficult to find room for patients to return to hospital for the requisite three doses.

#### Hallam Hospital, West Bromwich.

Some interesting references to recent developments in the hospital system were made at West Bromwich on the occasion of the formal opening, on March 30th, of the new administrative block, x-ray department, and nurses' home at the Hallam Hospital by Sir William Willcox. The reorganization and reconstruction of the hospital, which is controlled by the West Bromwich Board of Guardians, has been in progress since 1925, when the old workhouse infirmary was renamed and became, by consent of the Ministry of Health, a self-contained institution. The Rev. J. Scarlett, chairman of the guardians, who presided at the opening ceremony, described the changes which had been brought about in modernizing the buildings and equipment, and in securing the services of a visiting medical staff, of whom the members of the board were proud. Hallam Hospital, he said, was not intended in any way to enter into competition with the voluntary hospitals, which he hoped would never die, but the guardians were compelled to make provision for cases for which no accommodation could be found in the voluntary hospitals. Sir William Willcox congratulated the guardians on their broad-minded policy, saying they had done something which would occupy the attention of the country, the Government, and the nation as a whole. They had set a fine example to the governing bodies of similar institutions, and he anticipated that what had been done in West Bromwich would be followed by a similar advance in hospital reorganization throughout the country. The hospital was run on lines exactly parallel with the most advanced of modern voluntary hospitals. Sir William Willcox further expressed the view

that there was great need and ample room for both municipal and voluntary hospitals; he did not believe municipal hospitals should be in any way subservient to, or in any way less efficient than, voluntary hospitals. He concluded by pointing out the value of the Hallam Hospital as a centre of medical education and research. Dr. Douglas Stanley, visiting physician, referred to the extraordinary wholehearted co-operation the medical staff had received from the committee and board responsible for the hospital. The committee had given the staff almost everything they required. A vote of thanks to Sir William Wilcoxon was moved by the Mayor of West Bromwich and seconded by the Mayor of Wednesbury. Figures quoted in the souvenir booklet issued at the opening ceremony demonstrate the increasing use which has been made of the facilities offered by the hospital. The number of patients admitted rose from 2,304 in 1926 to 2,963 in 1927, and the number of operations performed from 120 in 1925 to 690 in 1926 and 924 in 1927.

#### Coroners' Inquests in London in 1927.

The number of deaths reported to London coroners in 1927 was 7,478, as against 6,934 in the previous year, but only 4,442 inquests were held, as against 5,143 in 1926. Of the inquests 82 per cent. necessitated *post-mortem* examinations. A verdict of murder was returned in 21 cases, of manslaughter in 6, of suicide in 611—an increase of 11 on the figure for the previous year. Four inquests were held in connexion with executions. Deaths from want of attention at birth decreased from 57 to 27. The number of people who met their death by accident was 1,916, as against 1,760 in 1926. Injuries accounted for 22 deaths, and there were 60 deaths by drowning, as compared with 50 in the previous year. A verdict of "death from natural causes" was returned in 1,610 cases, and there were 27 verdicts of "cause of death unknown." The inquests on newly born children decreased from 146 to 108 (61 males, 47 females); there were 7 verdicts of murder of the newly born, and in 35 cases it was decided that the child was stillborn. Excessive drinking accounted for 30 deaths, an increase of 2 over the previous year. The total cost to the London County Council of inquiries made by coroners and of inquests held in 1927 was £31,444.

## Correspondence.

### STREPTOCOCCI AND PUERPERAL SEPSIS.

SIR,—The recent letter to the *Times*, supporting the view that real research work into the origin, etc., of puerperal septicaemia is required, calls for the support of all workers on the subject.

In some recent work on antiseptics which we have been conducting in this laboratory one aspect of this question has been emphasized. The usual standard for antiseptics is the Rideal-Walker test, or a modification of it, using the *B. typhosus* as the standard organism. In our work we have shown that the action on different organisms, and different strains of the same organism, varies in a marked degree, and that an antiseptic which may be efficient for *B. typhosus* may be quite inefficient for other organisms.

'Garrod' showed that this selective action was marked in experiments with *B. coli* and streptococci in faeces. Our experiments have borne out these conclusions. To take one example only: lysol, which is largely used in obstetric work, is almost ineffective in its action on some strains of streptococci, taking fifteen minutes to kill in a dilution of 1 in 100 in ordinary saline or distilled water, whereas in albuminous fluids the lethal power is considerably reduced. —I am, etc.,

J. M. BEATTIE.

Bacteriological Department, City Laboratories and  
University School of Hygiene, Liverpool,  
April 7th.

### RADIATED ERGOSTEROL AS A DRESSING FOR WOUNDS.

SIR,—In continuation of my note "On irradiated ergosterol as a dressing for wounds," published in the *British Medical Journal* of March 3rd (p. 339), I have endeavoured,

with Mr. F. Young's help, to ascertain whether any gain in weight occurs when ergosterol is irradiated.

*The Effect of Radiation.*—A film of ergosterol, 15 to 16 mg., thinly spread on a glass plate, 65 sq. cm. in area, was weighed before and after exposure to the ultra-violet rays from a mercury vapour lamp at a distance of 14 in. for forty minutes. The gain in weight of such a film after radiation was about 7 per cent. A corresponding cholesterol film, radiated in the same way, showed very little gain.

*The Effect of Ozonization.*—An ergosterol film was also exposed to ozonized air at room temperature for four hours. The gain in weight after ozonization was about 7 to 10 per cent.—that is, rather more than the gain which follows radiation. A corresponding cholesterol film, after ozonization, under similar conditions, showed only a slight gain, which was slightly increased by a second ozonization.

Thus a marked difference in the capacity rapidly to absorb ozone is characteristic of the two different sterols. In the case of ergosterol a saturation point seems to be reached after radiation for from thirty to forty-five minutes, depending on the thickness of the film and the activity of the lamp. Further radiation under the conditions mentioned above gives very little additional increase in weight. This saturation point is reached less quickly on ozonization than on radiation, and a slight gain may be recorded on a second ozonization.

Very little loss in the weight gained has so far been noticed in the treated films after exposure to the air at room temperature in either case. This means that the adsorbed or added oxygen is not released at any appreciable speed under such conditions. A chemical examination with the starch potassium iodide colour test, previously described, shows that the capacity for oxidizing potassium iodide is associated with this gain in weight, which follows both radiation and ozonization.

Recent observations by Rosenheim, and also by Windhuyis, have established the fact that the formation of vitamin D occurs independently of, and in the absence of, oxygen. It seems probable, therefore, that, as Dr. Rosenheim has suggested to me, the oxidation of the potassium iodide in the starch colour test is due to a peroxide (or ozonide) of ergosterol, and not to vitamin D. The fact, however, that ergosterol gains in weight on radiation, and that it is, under certain conditions, freely converted into vitamin D, while cholesterol does not gain appreciably in weight, and does not yield any quantity of vitamin D when similarly treated, suggests that some relationship does exist between the capacity for peroxide formation and the capacity for conversion into vitamin D. This difference in behaviour must depend on a difference in the structural constitution of the two sterols. Whether the formation of the peroxide represents a preliminary or, as seems more likely, a terminal stage or is merely a side reaction in the process of vitamin D formation, and what the optimum conditions may be for obtaining the maximum yield of vitamin D, are not yet fully known.

Finally, it seems probable, in the light of these observations, that the action of radiated ergosterol on wounds and granulating surfaces, previously described, may be due to the peroxide or ozonide of ergosterol rather than to vitamin D. This point, however, opens up important possibilities which require further investigation.—I am, etc.,

C. J. BOYD.

Leicester, March 26th.

### GALL-BLADDER INFECTIONS.

SIR,—If his account is meant to include all cases which clinically show the signs and symptoms of chronic, recurrent inflammation of the gall-bladder, then I feel that Professor Wilkie, in your issue of March 24th (p. 481), has not quite accurately represented the bacteriological side of the matter when he only discusses a series of cases in which the great majority of which there was a primary intramural infection by streptococci, organisms of the coliform group occurring usually as secondary invaders. That low-grade intramural streptococcal infection is not uncommon there seems to be no doubt. Having recently examined histologically and bacteriologically some sixty gall-bladders removed from patients who, while in the physicians' care, were held to show every sign of chronic cholecystitis, I believe that just over one-third of them were of the streptococcal type which Professor Wilkie describes. The bile was sterile, but in eight what

appeared to be streptococci could be seen in the walls: in four of these positive streptococcal cultures were obtained, and the histological appearances of the remainder were similar, although no organisms could be grown.

On the other hand, my series contains also nineteen cases in which the gall-bladder wall, particularly the mucosa and the tissue subjacent to it, showed chronic inflammatory changes, possibly a little more active than those associated with a very chronic intramural infection, but entirely without histological evidence of old preliminary bacterial invasion deep in the wall. From these nineteen gall-bladders organisms of the coli-typhoid group were readily grown, two of them giving typical pure cultures of *B. typhosus*. It seems to be quite clear that intramural streptococcal cholecystitis is more common than was formerly realized, but I do not think that this fact provides a reason for describing as uncommon the type of case long recognized as due to direct primary infection of the gall-bladder and its contents by organisms of the coli-typhoid group, which may reach the biliary tracts via the blood stream and liver. Ascending infection of the bile ducts may on occasion occur, though the finding of coliform organisms, especially in the gall-bladder bile obtained by duodenal intubation, does not, of course, give any indication as to the origin of the infection, but simply shows its presence. Nevertheless, the material obtainable by duodenal intubation in the two types of cholecystitis is strikingly different, and may therefore help the decision as to whether biliary antiseptics and biliary drainage will be beneficial or whether surgery should be resorted to at once. In the intramural streptococcal type of cholecystitis nothing abnormal is found in the bile unless the process of stone formation has begun, in which case fragmentary cholesterol crystals are quite common. In the coli-typhoid infections the bile not only contains the infecting organism, but also much more epithelial debris from the biliary tracts, particles of solid bile pigment, and sometimes a few leucocytes. If the incidence of the purely intramural infections were as high in all patients showing clinical evidence of chronic infection of the gall-bladder as Professor Wilkie suggests, one would not, I think, so frequently see obvious improvement follow the administration of large doses of hexamine, which can affect only the contents of the gall-bladder and the mucosa.—I am, etc.,

London, S.W., April 3rd.

F. A. KNOTT.

#### TREATMENT OF ACUTE PNEUMONIA.

SIR,—I have read with much interest and pleasure Dr. Maidlow's letter (February 11th, p. 238). It was so practical, so full of common sense, and so different from many communications suggesting, often without sufficient trial, all sorts of new remedies for various diseases, which only too often dishearten the great bulk of the medical profession who try them. I have had a very long and varied experience both in hospital and private practice, and the outcome of all this practical investigation is much the same as Dr. Maidlow's—namely, disappointment, especially at the results obtained in pneumonia by the new methods of drug treatment. In the majority of such cases Nature will effect a cure with very little assistance if only given a fair chance, and this is nearly always given her by the experienced physician. What we find in practice is that Nature's efforts are often interfered with and destroyed by the too frequent visits, repeated examinations, and over-zealous physicking of the medical attendant. Doctors seem to forget that pneumonia is a specific fever in the great majority of instances, with a local manifestation, and will cure itself by a well-marked crisis in eight or nine days if not unduly interfered with. Nature's method of treating pneumonia should be applied to numberless other ailments, which will assuredly result favourably if only left alone and properly nursed. In nearly every medical journal we read of new suggestions and new remedies, which the experienced physician notes, but disregards, unless backed by the highest authority. Many of these articles express very divergent opinions on the same subjects, and thus tend to confuse instead of help. In no complaint is this difference of opinion more marked than in pneumonia.

Sir James Barr, in this month's *Practitioner*, rejects the use of oxygen in the treatment of pneumonia. He is right; it is a most expensive expedient, and I have never seen it of the least use. The need for it arises frequently from a distended right heart, and the right treatment is blood-letting. I have known the most remarkable results follow the latter expedient, whereas I have never seen oxygen give more than a very temporary relief. Dr. Maidlow advocates in the treatment of pneumonia many small remedies which certainly would add greatly to the comfort of the patient. In this connexion, except in the most debilitated patients, I recommend the use of a commode and not a bedpan; the latter always induces straining and unnecessary exertion, whereas the former causes a freer movement of the bowels, saves much discomfort, and is more cleanly. It is extraordinary how many complaints will yield to simple and common-sense remedies and healthy surroundings without resorting to the innumerable vaccines and serums and the hundred-and-one nauseous drugs, which generally do more harm than good. Our profession, through the recommendations of chemists, is rapidly losing touch with the writings and textbooks of our best authorities, and is getting under the spell of the treatment of every variety of diseased conditions by new vaccines and serums.

Dr. McCormick (March 3rd, p. 376) thinks that Dr. Maidlow's letter breathes the spirit of a bygone age. It does nothing of the kind; it mentions facts, not theories, and gives good reasons for the opinion he expresses. The physicians in the past gained their knowledge mainly from clinical research and experience. The young physicians of to-day base most of their opinions not at all upon clinical facts, but on x-ray observations and the reports of various bacteriological authorities and chemists. In the same issue Dr. Robert Hutchison writes (p. 335):

"It may be doubted whether ordinary bedside observation of the signs of disease is as good now as it was a generation or two ago. . . . There is, I believe, a real danger lest the increased use of laboratory tests, x-ray examinations, and other short cuts to diagnosis should lead to a neglect of the information to be obtained by the skilful use of the unaided senses, and to a comparative atrophy of these from disuse."

This is exactly what is taking place in the training and education of our young surgeons and physicians; they are being taught to rely too completely on the extraneous aids to diagnosis without closely examining the clinical features of disease; upon which all accurate information should be based in the first instance.—I am, etc.,

Omagh, March, 1928.

EDWARD THOMPSON, F.R.C.S.I.

#### THE NEW PORTRAIT OF JOHN HUNTER.

SIR,—The incomparable Oliver Goldsmith represents George Primrose, the eldest son of the Vicar of Wakefield, as asking his art-dealing cousin how to become a "cognoscento." Nothing more easy, says the cousin; first of all, you must always find fault.

This wonderful new portrait of Hunter is the most interesting we possess; for it shows him exactly as he lived and lectured, wart and all (*pace* the shade of Oliver Cromwell). But it has had to fight a hard battle ever since it appeared upon the wall of Christie's saleroom. At first the cognoscenti said it did not represent John Hunter; this denial has, however, been blown to the winds; and now Mr. C. F. Beadles comes forward and asserts that the painting is not by Gainsborough, and that its late owner, Mr. McCormick, "did not consider it worthy to be labelled as by that artist." I am sorry, for Mr. Beadles's sake, to have to state very plainly that this is an absolute misstatement of fact. On my table, as I write, is a 23-inch label which was screwed on to the frame when the picture was put up to auction:

"John Hunter, F.R.S., 1728-1793. Physiologist and Surgeon. By Thomas Gainsborough, R.A., b. 1727, d. 1788. (British School.)"

Mr. Martin alone knows why no notice was taken in Christie's catalogue of this tablet, and why the picture is there attributed to "Seton," a name which, of course, conveyed nothing to me. It now appears that this cabalistic word meant "John Thomas Seaton." It is, however, a pure surmise to attribute the portrait to this artist. To support his *nil admirari* attitude Mr. Beadles instances the neglect of the picture at the sale by the

expert dealers. Did they neglect it? And if they did, has Mr. Beadles forgotten the great Huntington picture trial of 1917? Here expert dealers had to refund over £20,000, the price they had obtained for "the most beautiful and attractive Romney" a great so-called expert swore he had ever seen. Next day the picture was dramatically and incontestably proved to be by Ozias Humphry! My friend the late Mr. Milner thought this portrait of Hunter might be by Bone. Mr. Martin and Mr. Beadles think it may be by "Seton"—I beg pardon, John Thomas Seaton; so that it is evident the greatest experts may differ. The late owner of the picture and I think it is by Gainsborough, and there for the present the matter may be left.—I am, etc.,

London, W., April 2nd.

G. BUCKSTON BUOWNE.

#### INJECTION TREATMENT OF VARICOSE VEINS.

SIR,—In a portion of Dr. Dewey's letter to the *British Medical Journal* (March 24th, p. 522) he asks me if I meant in my letter, published in your issue of March 10th, that in all cases of thrombosed varix there is no fear of clots getting into the general circulation.

There is great danger, and death occurs from clots breaking off and getting into the general circulation from thrombosed veins. This is, however, only to be looked for in disease coupled with infection of the vein. The production of a chemical thrombosis is brought about in quite a different way. Sclerosing injections—many of them are anticoagulants—destroy only the inner wall of the vein primarily; later a clot forms in the same way as it does in a ligatured vessel—that is, the destruction of the endothelium at the site of the ligature; at this point a thrombosis forms. If a ligatured vessel becomes the site of infection the thrombus may disorganize, soften, break down, and get into the general circulation as an embolus or emboli. In aseptic conditions no such thing takes place—emboli never form. Infection, therefore, must be considered as the *sine qua non* to the formation of emboli. With strict asepsis and in properly selected cases there is no fear whatever of producing emboli by the present methods used for the injection of varicose veins.

Dr. Douthwaite in the latter part of his letter (March 24th) speaks about the practice of putting patients suffering from spontaneous phlebitis to bed.

If the spontaneous cases are due to injections I find that patients do very well getting about, but in the case of severe reaction rest on a couch with the limb in the most comfortable position possible for a day or so is all that is necessary.—I am, etc.,

T. HENRY TREVES BARBER, M.D., B.Sc.

London, S.W.7, March 25th.

#### SMALL-POX AND "CASUALS."

SIR,—Dr. Duncan Forbes, medical officer of health for Brighton, in a letter to the *Times* of March 23rd, called attention to the spread of small-pox in the south-eastern counties, and said that "this spread is in great part due to the uncontrolled movements of tramps known to have been in contact with the disease." It is, of course, generally admitted that the tramp in the common lodging house is a far greater danger than one in the casual ward, where at least some sort of supervision is given. To state the problem is to suggest the remedies which can be applied by the Minister of Health under the great powers given him by the Poor Law Act, 1927, without waiting for any further Act of Parliament. It is possible that an Order or Regulation of the Minister will be needed to back up his circular.

In the provinces some 137 casual wards have been closed—mostly recently—by the Ministry and the local boards of guardians. In other words, 137 places where the tramp could go with comparative safety to the public have been taken away, and many tramps have been driven to sleep in common lodging houses, or in places where there is and can be no proper supervision. A large number of these wards should be reopened at once. The Minister has the power to do so under Section 69 of the above-mentioned Act. The Minister should issue to all boards of guardians

a circular of a far more effective nature than the circular of January 23rd, 1928 (*Journal*, January 28th, p. 154). The tramp should be examined by the doctor, not only before he goes out, but when he comes in. Otherwise during his two days' detention he will have plenty of time to infect other casuals, who will proceed on their journeys before the doctor makes the tardy inspection suggested by the Ministry of Health. "Contacts" should not only be "offered vaccination," but should be given some trifling inducement to submit to that operation, and told that if they remain during the necessary period they would be given decent food and accommodation, and not treated as casuals.

May I conclude with a special word as to the safety of London? Practically all the closed wards on the routes to London, at least within thirty or forty miles of the metropolis, should be opened. It should be so arranged as to distances that the destitute wayfarer will have no temptation to go to the common lodging house or "sleep rough." If at each casual ward two medical inspections are made, and the other precautions taken, the risk to London will be enormously reduced. By a wonderful oversight stone-breaking has been made one of the tasks for the metropolitan casual wards. A slight discussion on the subject took place in the House of Commons on March 15th. The object is, of course, to deter men from coming into these wards; but the effect is to keep men who may be infected with small-pox from coming into decent clean quarters, where infection would be promptly dealt with. What I have said as to the routes to London is applicable to other towns, and the folly of the London stone-breaking is also visible in some places in the provinces.—I am, etc.,

J. THEODORE DODD,  
Barrister-at-Law.

St. Leonards-on-Sea, March 27th.

P.S.—Since this was written a memorandum has been issued, but I have not yet had an opportunity of seeing it.

\*\* As stated last week (p. 609) the Minister of Health has extended the period during which casuals must be examined for a further three months. The circular announcing this decision recognized the danger of dispersing persons who had been exposed to infection when casual wards are closed owing to occurrences of small-pox. Mr. Dodd's suggestion applies, of course, to casual wards closed for other reasons. The circular reminds guardians that their powers do not extend to detention of persons who, although they may have been exposed to infectious disease, are not actually suffering from it, even though they decline to be vaccinated. On February 25th (p. 324) we gave details of the outbreak of small-pox in London, mainly in a Poor Law institution.—Ed. B.M.J.

#### EFFECT OF THE BIRTH RATE ON THE AVERAGE AGE AT DEATH.

SIR,—May I call attention to what appears to be an oversight in the popular appreciation of the increase in the average length of life? This is commonly taken to be synonymous with the average age at death, but really the two things are for distinct consideration. The average age at death in any year is easily estimated from statistics derived from death certification. Other factors affect the estimate of the length of life justly to be expected for each newborn child.

Generally, the increase of the average age at death is attributed alone to the decrease in the death rate, whereas it is really affected also by the decrease in the birth rate, which during quite a long period of years reduces the relative number of persons living at the lower ages, and so creates an elevation in the average age of the population and the average age at death.

The elevation of the average age of the whole population, or the relative increase in it of the older portion, or its ageing by reason of a lessening in the number of births, is making, or will presently make, a difference in the relative prominence of those activities which pertain to youth and age. Of itself it would seem to be a cause, during the period of its operation, of still further lessening the birth rate.—I am, etc.,

J. H. GARRETT, M.D., D.P.H.  
Cheltenham, March 28th.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

LAST week the House of Commons, before rising for Easter, read the National Health Insurance Bill a second time, sent it to a Standing Committee, and passed a money resolution attached to the bill. The House also debated rural housing and Poor Law relief. It will reassemble on April 17th.

### National Health Insurance Bill.

#### Debate on Second Reading.

On April 3rd Mr. CHAMBERLAIN moved the second reading of the National Health Insurance Bill. He said that this national health insurance scheme was a tremendous undertaking. Under it, to-day, some 16,000,000 people were insured in this country, each of them paying a weekly contribution, which individually amounted to only a few pence, but which, when added together, formed a tremendous aggregate of about £25,000,000 a year. In such a huge scheme it could not be wondered at if, from time to time, it was found capable of improvement. And if, all the time, there were constant demands for the simplification of its machinery. The bill was a further attempt at simplification of machinery, although it contained some improvements of substance. It was founded principally on a recommendation of the Royal Commission appointed in 1924, under the chairmanship of the late Lord Lawrence of Kingsgate. There was on the order paper a Labour amendment for the rejection of the bill, but Mr. Rhys Davies, who would move it, seemed to have found nothing to condemn or even criticize in the bill. The hon. member had, however, sought to found his motion for rejection on what the bill omitted. No doubt Mr. Davies was aware that the bill had been approved by the Consultative Council, and that the approved societies generally would be grievously disappointed if the bill did not become law.

Mr. Chamberlain then explained the bill in detail. The prolongation of Insurance Act would be abolished and a new scheme would be substituted, under which all the penalties for arrears of contribution incurred because a man was genuinely unable to find employment would be abolished. Clause 1 contained the largest concession to insured workers and the biggest simplification of machinery that had been introduced into the national health insurance scheme since its inception. Under the new arrangement for prolongation of insurance any genuinely unemployed person would be retained in insurance after having ceased to pay any contributions whatever for between two and a half and three years. That was a provision which would meet all the ordinary cases of unemployment likely to arise. Again, in the case of a man hitherto continuously insured for a period of ten years who, after reaching 60, fell out of employment, he would be kept in insurance year after year, providing that in each year he could show that during the preceding year he was available for, but unable to obtain work. This would prevent any man who had been in regular employment for a substantial period losing his old age pension because of any difficulty he might have in finding employment after he became 60 years of age. Referring to additional benefits, particularly dental and ophthalmic benefits, Mr. Chamberlain said that this was a very important matter. Its importance lay particularly in the fact that these treatments were largely preventive as well as curative in character, and that the large sums, amounting to about £4,000,000 a year, which were now being spent by the approved societies on dental and ophthalmic benefits might be expected in due course to bring their reward to the approved societies by the improvement in general health which they were calculated to produce. It was a striking fact that, while the administration of medical benefit was carefully safeguarded in the original Act, and conditions were laid down in the body of that Act for that administration, and the Ministry was given power to make regulations still further to elaborate those provisions, nothing of the kind was to be found in the original Act in regard to additional treatment benefits. That could not be wondered at, because those benefits had not then reached their present importance; but now that they had arrived at their present pitch of development it was very necessary that some similar care should be taken in regard to dental, ophthalmic, and other additional treatment benefits to see that the money was properly expended and to the best advantage of the insured people. In Clause 14 (3) the Minister was given power to make regulations governing the administration of any additional treatment benefit, and the general arrangement of services under which the treatment was to be provided. It was widely recognized in national health insurance circles that something of the kind was required. Taking dental benefit, for instance, the Consultative Council, recognizing how necessary it was that the approved societies should be able to command an adequate dental service at a reasonable price, recommended the establishment of a joint committee to deal with this matter. Accordingly, a committee composed equally of the dental and the approved societies, known as the Dental Service Committee, had been set up to regulate the conditions of the dental service, and the profession, and to ensure the proper working of the service. On the whole, the joint committee was to be congratulated on having worked with a considerable amount of success, but there had been this difficulty—that it was not a statutory body, that it had to work by persuasion, and could not work by authority. There had been a considerable amount of prejudice, and failure in some places to get the best service possible, on account of the lack of authority on the part of the Dental Benefit Joint Committee. One of the things which

he desired to do was to make regulations, under the clause to which he was referring, which would enable him to give that authority to the joint committee, to ensure that any decision that it came to should be made binding upon all the approved societies coming into the scheme.

Dr. VERNON DAVIES: And upon the dentists?

Mr. CHAMBERLAIN: Yes. They hoped to get a similar committee set up to deal with ophthalmic additional treatment benefit. Another matter on which it was necessary that he should have power to make regulations was in regard to dental clinics. Something appeared to have aroused a certain amount of confusion in connexion with this subject. Judging from his own correspondence, he was convinced that many members of the dental profession had altogether exaggerated what was in contemplation. He said at once that there was no intention of doing anything more at present than embarking on an experiment or two in order that they might thoroughly explore the advantages or disadvantages of the system of dental clinics. The argument in favour of the clinic was that where they got a dense population and could rely on a steady flow of patients, they could get, in a clinic, a standard of equipment and specialization among the staff which it would be unreasonable to expect from a single practising private dentist. He supposed that the argument against the clinic was that it was going to drive out the private practitioner and set up a monopoly. The matter had been discussed by the Dental Benefit Joint Committee, and they did not come to any conclusion except this—that they thought it very desirable that an experiment should be made, so that they might see whether the advantages outweighed the disadvantages, or vice versa. If the bill passed through Parliament, it was his intention to make regulations for the setting up of such experimental clinics, one or two, perhaps, in London. He repeated that in no circumstances could he contemplate abolishing the free choice of dentists. No one must be compelled to go to a clinic if he would rather go to a private practitioner. It would certainly be a condition of the acceptance, even of an experimental clinic, that there should be adequate representation of the profession on its management.

Dr. DAVIES: Are we to understand that the consent of the local dental profession will first of all be obtained before the clinic is established?

Mr. CHAMBERLAIN: No; I do not think I can give any assurance to that extent, certainly not at this stage. But I do not anticipate that we shall have any difficulty in selecting the most suitable place for an experiment of this kind, where we shall not arouse any violent feeling of hostility on the part of private practitioners in the neighbourhood. With regard to deposit contributors, under Clause 10 those people who, on account of bad health, could not get into an approved society, would be formed into a new section of deposit contributors, to be called the Insurance Section. They would be entitled, not only to the equivalent of their own contributions plus the State contributions, but they would be entitled to all normal statutory benefits given under the original Act. If in the committee stage, Mr. Chamberlain added, amendments were put forward with the object of improving the bill, they would receive most careful and sympathetic consideration from the Government.

Mr. Rhys DAVIES moved: "That this House, whilst prepared to welcome the National Health Insurance Bill, cannot

assent to the bill which fails to recognize, in the light of the necessity for making the scheme more national in character by establishing the right of entry to many persons now excluded, neglects to make better benefits possible by restoring the State contributions of which the National Health Insurance Fund has been deprived, and fails in many respects to carry out the recommendations of the Royal Commission." He said that it was a travesty to state that this bill was brought forward as a result of the recommendations of the Royal Commission. Out of 122 separate recommendations of the Commission the bill contained only 32. In fact, the bill was purely an administrative measure, and the big questions affecting the health of the 16,000,000 insured people of this country were left entirely untouched. He said he would like the Minister to explain what was meant by Clause 3, dealing with "medical charities," particularly in South Wales. He understood that some of those medical charities were doing excellent work, and he hoped he might be pardoned for a little suspicion that the medical profession were influencing the Minister of Health unduly in that respect.

Dr. FREMANTLE: Never.

Mr. DAVIES said that before they could consent to the abolition of these medical charities he thought they must secure evidence as to whether there was any abuse of the privileges granted them under the original Acts. The two most important recommendations of the Royal Commission related to the pooling of surpluses and to the abolition of insurance committees, and this bill touched neither. The Minister seemed to have avoided Clause 11. The Royal Commission was very emphatic that something more should be done in connexion with maternity benefit and the case of married women in general under the national health insurance scheme. Clause 11 did make the position of married women very much clearer, but it did not touch those issues raised by the Royal Commission—the terrible tragedy of maternal mortality in this country, about 3,000 women dying annually in childbirth. This bill did not touch that problem in the least. He wanted the Minister to safeguard the interests of the insured persons by making it compulsory on the approved society to include words to the effect that if the insured person failed to go to a clinic he could still choose his own dentist or optician. He had no criticism to offer on the clause relating to penalties except one. He hoped that the Minister, in dealing with penalties by regulation, would see that whatever penalties he inflicted on the administrators of approved societies and insured persons he would

inflict similar penalties on the medical practitioners, dentists, and opticians who might transgress the law. Some members of the medical profession were issuing medical certificates definitely with a view to increasing their panel practice, and as far as he knew there was no provision to deal with cases of that kind in this bill. If it was proposed to give the Insurance Committees ultimately the administration of some benefits which were to-day administered by approved societies the Minister of Health would find himself in a difficulty with the Consultative Council. If there had been any abuse at all in connexion with the administration of national health insurance he was convinced that it occurred under Section 26. What had been done had been done probably strictly within the wording of the section, but it had not been done very honourably. He supported the full repeal of that section. If any approved society wanted to do anything by way of clinical work or granting money towards charities or hospitals it ought to do it cleanly and above board. The Royal Commission recommended that the scope of maternity benefits should be extended to cover medical and midwifery services in addition to cash benefits. It would be interesting to learn why that provision had not been included in the bill. The Commission further recommended the extension of the scope of medical benefit in respect of dependants of insured persons in receipt of sickness or disablement benefit, to improve provisions at the time of pregnancy and childbirth, the provision of dental benefit as a normal benefit, and, above all, that the insured population should be entitled to specialist services as well as ordinary medical practitioner services. Were it not for the fact that the State grant had been reduced the majority of societies would have been able to pay for specialist services.

Sir KINGSLEY WOOD said the fact that there had been no provision made in the bill for specialist services had nothing to do with the Economy Act.

Mr. DAVIES said that the bill was a very small contribution to the problem of national health insurance. It did not assist in the solution of the health problems of the country. What about cancer and rheumatism? Nothing was done in the bill to deal with those diseases. When they compared the bill with the recommendations of the majority of the Royal Commission he thought that the Opposition were justified up to the bill in moving this amendment and carrying it to a division.

Mr. WHITELEY seconded the amendment.

Mr. WHITELEY seconded the amendment.

Dr. FREMANTLE said that there were certain points which naturally concerned very closely the medical and dental professions, and he wished to voice one or two of the feelings on those points. The medical profession generally would bless the bill, in certain parts strongly, and in other parts they would find it good in less degree. He wished to call attention to the fact that the dental profession were naturally very much concerned, but they would be partly reassured by the statement which the Minister had made that afternoon. He hoped that possibly the Parliamentary Secretary to the Ministry of Health might be able, in replying later, to give the further assurances that were required. He (Dr. Fremantle) could speak perhaps with greater conviction for the dentists, inasmuch as it was a friendly profession for which he had no direct responsibility, but he had this from the body representing the dental profession. There were three points which they hoped to see definitely established in the statement that afternoon. The first was that the insured person should have the same freedom of choice of his dentist as he enjoyed with regard to his medical adviser. He thought that the House had had a very definite categorical statement that would be satisfactory to the dental profession. The second point was that the acceptance of any agreement as to fees and conditions of service arrived at after free negotiation by representatives of approved societies on the one hand, and of the dentists on the other, should be subject to the approval of the Minister. The difficulty was that they met with collective bargaining everywhere. Unless the results of collective bargaining were made to hold with all parties concerned, especially with those who were less inclined or less able to carry out a bargain, the main object of collective bargaining fell to the ground. The third point was that there should be no lay interference with the professional discretion of the dentist in the treatment of his patient. Always the criticism by the professional men of the approved societies was that instead of simply confining themselves to administration the approved societies interfered with the actual professional treatment, which only a professional man was really able to control and to criticize.

Sir KINGSLEY WOOD here asked Dr. Fremantle to explain a little more what he meant.

Dr. FREEMANTLE said that he meant that the difficulty of any lay control of professional persons was that in these matters they did interfere with the actual professional side. It was for that reason that they had their supervising officers. The doctors were naturally very sensitive. He thought that was really the only reason why sometimes there was friction between the professional men and the approved societies. It was for that reason that one could not accept the amendment that the societies should be done away with and their duties raised the old original criticism that was levelled against the Insurance Bill. It was obvious that approved societies could not properly administer these medical matters. The Insurance Committees were formed in order that they might get a better idea of the benefits to be administered. It was quite true, also, that the Royal Commission suggested that the duties of the Insurance Committees should be distributed to the appropriate local authority. That proposal was not, as Mr. Rhyds Davies had said, to refer these duties to the approved societies. It was to break up these duties and distribute them to the appropriate local authorities. He supposed that the reason was quite clear.

The whole question of local government was now the subject of discussion by a Royal Commission, and they must wait for the result of that before they could see how the local authorities were going to be so arranged that they could properly have those duties placed upon them. When they got the whole subject of d up and put on an ordinary and ped to have this question of the future decided. He was quite sure that the

decided. He was quite sure that the functions of the Insurance Committees ought to be blended with those of the health authorities generally. One of the main criticisms of the insurance system was that, whereas it was largely introduced by Mr. Lloyd George as a measure for the prevention of sickness, it had failed in the prevention of sickness to a very large extent. The amount of sickness among insured persons remained very much the same, although he believed that the kind of treatment applied had curtailed each case of sickness to a considerable extent. The system certainly gave relief, but for prevention it was of very little advantage. One of the objects put forward in connexion with the original bill was definitely to link up the question of prevention and the question of sickness by making a special provision by which, when any particular area was found to be suffering from a very excessive amount of sickness in any one respect, steps could be taken at once to turn the whole services of the Insurance Act on to that particular area. That had been found to be impracticable. Why? Because the measure was introduced originally independent of the existing health organizations. This was a danger that they constantly had in that House. They seized upon a new idea; they introduced a new bill; they introduced a new scheme of organization, with a new set of committees or even of actual authorities, and a new set of officials all the way through, and they added to their burdens while diminishing certain others. They had to use the actual machinery they had, and to improve it. He thought that local authorities might be used as the central authority for administering medical benefit under this Act.

There was one special form of benefit which he was sorry was not provided for as an additional benefit. That was attendance in cases of maternity. The answer of the Parliamentary Secretary would be that maternity benefit was provided by a money payment to the mother, who was responsible for providing the midwife or having maternity services. The objections to it were fairly obvious. In too many cases the money was required so urgently for other purposes that it was not sufficiently used for the midwifery services that were so necessary. He was glad that a committee was to be set up to inquire into the training and supply of midwives. When that committee reported he had not the least doubt that it would show that for a long time the number of midwives in the more scattered parts of the country had been diminishing, and that there was an immense difficulty in getting women to go into that important service. They had to record at the present time the yearly loss of 3,000 to 4,000 mothers as the result of childbirth, and they must, therefore, take some action which would increase the midwifery services of the country. They would not be able to get a better service in this respect unless they could make the profession attractive to the type of educated girl who would want to fulfil these duties properly. It really came down to a pecuniary benefit, and he would like to see some provision introduced into the bill which would enable a fund to be set aside for the general purpose of improving the remuneration of midwives. He hoped that the preventive aspect of insurance might be always kept uppermost, and that, as they worked this system during the course of years, they might see in what way they could use this sum of £25,000,000 to £30,000,000 a year, not merely for the relief of trouble, but to preventable sickness and disease.

to 250,000, for the prevention of preventable sickness and disease. Mr. HAYPA, in supporting the amendment, urged that the bill should make provision for family medical benefits. This question was a very important one for many reasons. He did not have become a very important one for many reasons. He did not know whether, if all the surpluses accruing to the approved societies were pooled, they would provide a sum sufficient to give medical benefit to the dependants of insured persons. He wished to call attention to a question of administration. Approved societies sent a large number of those people on sickness benefit to the regional medical officers for examination. That was done in the interests of the benefit fund of the approved society, but the payment of the expenses incurred came from the administrative fund of the society. Such payments should be allowed to come from the benefit fund itself, because if they were to flow continually from the administrative account the administration was likely to be affected, and they would not get that efficient supervision which was desirable. He suggested, also, that there should be one all-inclusive scheme, amalgamating all the present social services, under separate departments. That would avoid constant piecemeal legislation.

the inherent right of every insured person. In the North of Ireland medical benefit was not given, and the result was very unsatisfactory. It was suggested by some societies that they ought to have the right to exclude members in Northern Ireland from participation in general valuation until Northern Ireland brought in a system of medical benefit. The view they put forward was that the clause was unfair to their members in the English and Scottish societies which had members in Northern Ireland. He hoped that the Minister of Health would consider that question. The overwhelming opinion expressed by the people concerned was against the abolition of Insurance Committees.

Mr. MORGAN JONES said there were in South Wales institutions known as miners' medical aid societies. There was a considerable measure of apprehension among them as to what precisely the Minister of Health sought to do through the medium of Clause 3 of the bill. These societies had existed for a very long time, and after some difficulty were recognized seventeen years ago at the passing of the original Act. He believed they had something around 40,000 members, and if they included dependants the number would exceed 100,000 for whom medical services of various kinds were being provided. But they had had to face opposition from the British Medical Association, and also, they claimed, from the Insurance Committees. These bodies operated very largely on co-operative lines. The objection came, he believed, generally from the British Medical Association—and there had been pretty severe and sustained fights on the issue—that these societies had a larger measure of lay control even than was found under the system of Insurance Committees. He did not want to develop an attack on the doctors generally in this matter, but he was entitled, in defence of his constituents, to submit a case in support of these societies. They drew a contrast between the treatment meted out to these medical aid societies and that meted out to private panel practitioners, and the contrast was one which induced them to believe that the scales were heavily weighted against these medical aid societies largely because they were subject to the ban of the British Medical Association.

Dr. DAWKINS STURTS said that members on his side of the House were all agreed that the bill, so far as it went, was desirable, but it did not go to anything like the extent they thought was called for in any amendment of the National Insurance Act. As a response to the recommendations of the Royal Commission the bill was seriously inadequate. The Minister of Health and his department were not primarily to blame for that. They found here, as in connexion with so many other matters, the hand of the Treasury, which prevented from being done so much that the House felt ought to be done. Economy in these days was necessary, and the Treasury must exercise restraint in many directions, but the health of the people was one direction in which any so-called economy was misplaced, and where true national economy was to provide adequately for health and prevention of disease. If the lowering of the State grant had not prevented the provision of specialist benefit, why was it that we had not got it, and that there was no early prospect of it? The present position in regard to specialist benefit for an insured person requiring a consultation or operative treatment was exactly the same as that of an uninsured person. Unless it was an urgent case, which would be admitted to the voluntary hospital immediately, he came on the hospital's waiting list, and had to take his turn, with the consequence that treatment was delayed beyond the time when it would be of the greatest advantage. A condition of affairs which left the insured person dependent on that source for specialist benefit was obviously unsatisfactory. Ordinary ailments could be dealt with by the general or panel practitioner. The more serious cases might require operative treatment, the very latest laboratory appliances, x-ray or light treatment, and other aids from which, at present, the insured person was shut out. Yet here we had a scheme which purported to be a national scheme for the provision of medical service for the insured persons who contributed to it, and surely the Royal Commission was right in pointing out that so long as specialist treatment was withheld the system was unsatisfactory and did not meet the needs and the rights of its members. The question was obviously linked up with the hospital question, which this bill did not tackle at all. The voluntary hospitals had repeatedly made requests for allocations from the insurance fund proportionate to the number of patients they treated, but all they had here was a permissive clause which would enable societies to make contributions to hospitals. Before the Economy Act was presented to the House certain approved societies did make contributions to hospitals, but since that Act had come in it had been difficult or impossible for them to do so. Now they were to be permitted to give donations to count as medical benefit; but that would not meet the case. Either an allocation of money per head or some other financial arrangement between the insurance fund and the voluntary hospitals would be necessary. It was desirable for two reasons: in the first place, in order that the insured persons should not, as now, get specialist treatment as a charity, and, secondly, in order that the voluntary hospitals, or even, as they expected might be the case soon, municipal hospitals, should be assisted to carry on the difficult task of finding the necessary funds. He commended Dr. Fremantle's suggestion that through the national health insurance organization means should be found for training and supplying more midwives than were at present available. The existing insurance scheme was not adequate in the matter of sickness benefit. While there was something to be said for the flat rate system, it would be found that almost all other countries had a higher rate of sickness benefit than we had. He was glad that the Minister of Health had relieved the minds of many members to a large extent by his statement about dental benefit. It was desirable that the Dental Joint Committee should be made a statutory body. It was very important, from the public point of view, as well as from the point of view of the dentists,

that there should be a free choice for patients, and he was glad that that privilege had been preserved. There was no doubt that if dental benefit were made an ordinary form of treatment, and if full dental benefit were given to all insured persons, the health of these persons would be very considerably improved. There were many diseases caused by bad teeth. A great deal of the rheumatic diseases, about which so much was heard in industrial life, and which produced a very heavy sickness rate with important economic complications, were really in form of chronic infection due to bad teeth. Therefore the expenditure on dental benefit was, in the long run, a very economical expenditure. The same applied to a lesser extent to the efficient treatment of the eyes. The supplying of proper glasses to people who suffered from eyestrain was very important. The fact should be emphasized that although the Royal Commission had recommended these additional benefits, and public opinion approved them, it was impossible to supply them without a restoration of the State grant which was given before the Economy Bill was passed into law. He very earnestly urged the Minister of Health to put up a stronger fight with the Treasury to ensure that economy was not practised on the health of the people. If this bill could not be sufficiently amended, he hoped another measure would soon be introduced, bringing in some of the more important provisions which the Royal Commission thought necessary. Many of them looked forward to the time when the normal task of an insurance medical practitioner would not be so much that of curing people as of examining them periodically, so that the earliest signs of disease could be detected. That comprehensive scheme could not be carried out until the extended benefits, now so much needed, were given. That, again, could not be brought about unless more money was brought into the scheme, which could only be done by a restoration of the proportion of the State grant which we had before the Economy Act was passed.

Sir H. CAUTLEY said that he viewed with great apprehension the steady increase in the amount paid out in sickness benefit all over the country. Unless some steps were taken to check this expenditure the whole scheme, sooner or later, would be jeopardized. The extensive unemployment of the last few years might account for some of this increase, but not altogether, because it happened that in the rural societies, where there had been no unemployment, the same symptoms existed. Probably it might be true that the increase of sickness benefit was greater in the large industrial centres which had been severely hit by unemployment. The scheme for the administration of sickness benefit rested entirely with the doctors, and the only control was the appointment of a medical referee. He did not think the system could be improved in that respect. The sole judge of when an insured person required medical service and should receive his certificate to get medical benefit must be the doctor, subject to the procedure relating to the medical referee. His suggestion to the Minister was that, if the doctor was entrusted with this responsible work, his position ought to be made, as far as possible, such that it did not conflict with his duty. He had, as his private patients, perhaps the man's wife and family, and if he lost that particular patient he lost the whole family. The same thing happened when a doctor had to certify the patient as being off benefit. His (Sir H. Cautley's) suggestion was that no one should be entitled to change his doctor without giving, say, three or four weeks' notice. In such cases as those to which he had referred, no doubt the fit of irritation would have worn off in a day or two, the person would have gone back to work feeling better, the whole thing would have blown over, and he would no longer have any desire to change his doctor. It had also been suggested to him that, in addition to notice, reasons should be required, but he did not approve of that. It would encroach on the free right of choice of doctor, in which he was a great believer. In the few societies with which he was directly concerned it had been found that in many cases where they had had to appoint a medical referee the patients had never gone to that medical referee at all, but had at once gone back to work. He asked the Parliamentary Secretary if the facts and information in his own office did not bear out the case he was making for this small alteration, and he hoped the Minister could see his way to make this reform, which was only common sense.

Dr. VERNON DAVIES said that the only way the Opposition could attack this bill was by making some obscure reference to a past raid on the insurance fund and by pointing out that the Minister of Health was very subservient to the Chancellor of the Exchequer. If that were true it increased his (Dr. Davies's) admiration for the Chancellor of the Exchequer if he had sufficient power to overawe or to guide the Minister of Health, because among the medical profession in this country the Minister of Health was not by any means regarded as a soft man. In fact, they found him rather difficult to deal with, and perhaps sometimes a little autocratic. With regard to the question of the medical aid societies or clubs, though he held no brief for the British Medical Association, he imagined that the objection it had maintained for a long time was that the system adopted by these societies put medical men under lay control. For some years now he believed the Association had taken certain steps to advise medical men not to apply for these appointments. What happened in these cases was that the medical man became the servant of a lay committee, who had power to dismiss him.

Mr. MORGAN JONES: Just as in the case of the medical officer of health.

Dr. DAVIES said that when they applied the Insurance Act to these medical aid societies they were in a different position at once, because the essential thing under the Insurance Act was that the patient must have freedom of choice of doctor, and he had not that choice in the case of the clubs. That was one of the great objections to the present system, but from all that he had heard he believed the standard of medical treatment which these medical aid societies had been able to give had been very high.

Personally, if he interpreted the clause rightly, he believed that the existing medical aid societies would not be interfered with, but he hoped that no new societies would be allowed to be formed. He did not agree with all that had been said on the question of maternity mortality. The greatest difficulty of all was not the lack of medical attendance or sufficient nursing attendance; it was the conditions under which the confinement took place which was the danger at the present time. A great move towards improving the condition of affairs would be to move such patients into a home, where they could be attended to by their own doctor and their own nurse. The essential thing in ophthalmic benefit was that the insured person should receive efficient and satisfactory advice, and the scheme which the British Medical Association had suggested to supply a sufficient number of trained doctors who would work at fees suitable for approved societies was the best way to deal with the subject. Ophthalmic clinics would be run by qualified men, who would give the best attendance and attention at the lowest price. He hoped that the Minister would not allow freedom of choice in that matter. An omission from the bill was in regard to the question of secrecy concerning venereal disease. The Minister knew that a guarantee or promise was made to panel practitioners that any information received in connexion with the treatment of venereal disease was to be held secret and inviolable. That guarantee or promise was made also to insured people, but now a judge in the High Court had decided that a panel practitioner could be compelled to disclose such information. The Minister ought to recognize this difficulty, and something should be put into this bill to meet it. He would ask the Minister to remember that there was a preventive as well as a curative side to national health insurance, and personally he had doubts as to whether the most economic way of getting rid of their surpluses was by establishing dental and ophthalmic benefits. At the ages when those benefits applied people as a rule were capable of full work, and could afford to pay the dentist and eye surgeon. More good would be done if instead of pushing their surpluses forward they pushed them backward, and did something to establish clinics for rheumatism, where they could get at the children and the young people after school age, when rheumatism was so dangerous, give sunbath treatment, and by other means help to establish a firm foundation of health at an early age, so that when they did enter industrial life they would be fitted for it in every way.

Mr. JOHN said that Clause 3 would abolish medical institutions. Speaking as one who had been connected with medical institutions for the last sixteen or seventeen years, he could not understand the reason for this. No complaints had been brought against these institutions, and they were subject to approval every year by the Insurance Committees. The medical institutions were really getting down to the fundamentals and objectives of the National Health Insurance Act itself, on the lines of attempting to co-ordinate the whole of the medical services. The benefits not only included what was contained in the regulations with regard to medical service, but the other benefits of the medical institutions. He was a member of a medical institution called the Mid-Rhondda Medical Aid Society, and in addition to the medical benefits contained in the regulations, such as proper aid and diagnosis of the complaint or disease, they had the use of the pathologists and second opinions with respect to expert specialist advice. Dr. Davies had been arguing for the right to increased benefits in the direction of pooling a certain proportion of funds for the payment of experts or specialists. That was not necessary with the medical institutions, which at present provided expert and specialist advice and special treatment. They also provided all the laboratory facilities, and dental and ophthalmic treatment and benefits. Everything necessary for the patient from the curative point of view was provided by the institution. Every member had a free choice of doctors. Every six months he could contract out of the scheme and go to the individual practitioner. Again, it was not true that the layman controlled the medical provision. He (Mr. Johns) had brought the qualifications of the medical institution before the House in order to appeal to the Minister not to dissolve these institutions.

Mr. A. GREENWOOD, supporting the rejection of the bill, said that the measure did not meet what was undoubtedly the national need. The existing system, within the limits laid down, would certainly be improved, but that system was not broad or large enough. The Minister ought to have turned his mind to the tremendous question of how to develop the health service to the maximum on its preventive side. The annual reports of the chief medical officers of the Ministry of Health and the Ministry of Education referred every year to the enormous amount of preventable disease which ultimately was found battenning on the health insurance fund. There was no more serious problem to-day than the standing disgrace of 3,000 deaths of mothers in childbirth, and the right hon. gentleman, if he had not been prepared to accept all the recommendations of the Royal Commission, should at least have ensured that the funds were available to deal with this great problem. The bill, however, left out one of the most important steps that ought to be taken in the extension of the national health insurance service.

Sir KINGSLEY WOOD, replying to the debate, said that all the leaders of the approved societies desired that the bill should have a speedy passage. But for the opposition of the approved societies it would be perfectly possible to put into operation the scheme of specialist services without bringing any additional funds into the national insurance system at all. No one had a right to say in that House that the specialist services were not being adopted on account of the Economy Act or of any question of finance. The Royal Commission went very carefully into the question of specialist services, and stated that if the approved societies would come to an agreement and pool their funds that scheme could be put into immediate operation without any further addition whatever, either by way of extra contributions or of

State assistance. To carry out the suggestion that medical treatment should be provided for the dependants of insured persons would mean bringing in altogether, including the people who were already in the scheme, a total of not fewer than 31,000,000 people, and the cost would be an additional £10,000,000 a year. He could assure the House that the Minister of Health would give very sympathetic consideration to any amendments moved in committee which were designed to improve the bill.

The amendment was rejected by 206 votes to 85, and the second reading was agreed to, the bill being committed to a standing committee.

On April 3rd Sir J. GILMOUR informed Mr. Stephen that he did not intend to abolish the Panel Committees appointed in connexion with the national health insurance scheme. The term of office of all Panel Committees in Scotland was extended by regulations till May 31st, 1929, and the Glasgow Panel Committee would, therefore, fall to be re-elected at that time.

#### Reorganization of Offices (Scotland) Bill.

In Standing Committee on the Reorganization of Offices (Scotland) Bill, on March 20th, an amendment to retain in existence the Scottish Board of Health was negatived by 27 votes to 18. The amendment was moved by Mr. JONSTON, who said there was no demand in Scotland for the abolition of the board system, and no resolution from any public authority had been produced in support of the change. Sir JOHN GILMOUR said there had been a number of complaints about delays in settling certain questions. In England the board system had been replaced by the departmental system. He himself had found the board system most inconvenient for carrying on the business of the country. He could not get from the chairman of the board in Edinburgh the direct and immediate advice which every other Minister could get from the head of his department in England. The abolition of the board would not prevent the interests in Scotland which were concerned with problems of health from direct consultation with the Department of Health. That department and the other new departments would continue to be in Edinburgh, as in the past, for as long as Parliament determined. Dr. SNYDES said the Board of Health was the most progressive Government department in Scotland or England, and its annual report was a model. Its activity in health matters, in supervising the health affairs of local authorities, and in the inspection of schools could not have been done so effectively by a single individual. At present the head of the medical department was on equal terms with the other members of the board, but if he was to be made merely a subordinate technical officer his work would suffer. Dr. ELLIOT said the principle of administrative concentration had proved sound, and the board system had fallen into considerable decay. The Act of 1919, which set up the board system, said that the board should at all times include two registered medical practitioners. That had not always been observed. They hoped in future to find in the department men competent to be technical heads. He saw no reason to suppose that the supply of officials from Scottish services would remain as great as in the past.

**Notification of Infectious Disease.**—On March 27th Mr. SHEPHERD asked the Minister of Health if he would consider the question of so amending the Infectious Disease (Notification) Acts that any case of suspected infectious disease would have to be reported without awaiting the results of a bacteriological examination, if such out awaiting the results of its early stages. Mr. CHAMBERLAIN said the negative. He added that the Acts in question did not require notification to be delayed pending the results of a bacteriological examination, and that notifications were frequently made solely as the result of clinical examination.

**Sanitation of Rural Districts.**—Answering Sir Robert Thomas, on March 28th, Sir KINGSLEY WOOD said that the sanitation of rural districts and the failure of some local authorities to exercise the appropriate powers under the Public Health Act of 1878 were the subjects engaging the attention of the Royal Commission on Local Government under Lord Onslow. The Ministry of Health awaited their recommendations, but could hold out no hope of Exchequer assistance towards such purely local obligations. He could not say when the report of the Royal Commission would be published.

**Small-pox.**—On April 3rd Sir KINGSLEY WOOD, replying to a question, said that during the thirteen weeks ended March 24th last 4,653 cases of small-pox had been notified in England and Wales. During that period approximately 100 Poor Law institutions had been invaded by the disease, and 16 cases had occurred in institutions certified under the Lunacy Acts or the Mental Deficiency Acts, but these institutions were only indirectly under the Minister of Health's control.

**Emission of Gases from Artificial Silk Works.**—On April 3rd Sir KINGSLEY WOOD informed Mr. R. Young that there had been cases of emission of unpleasant gases from some artificial silk works, but he was not aware of any injury to the health of residents in the neighbourhood of the works. The Minister of Health was having further investigation made.

**International Illumination Commission.**—On April 3rd Sir R. THOMAS asked the President of the Board of Trade if, in view of the importance of efficiency in artificial lighting, as affecting the eyesight of the nation, his department would be held in America the International Illumination Commission to be held in America in September. Sir P. CRUSSE-LISTER replied that his department would not be represented at the conference, but the Government would be represented through the Department of Scientific and

Industrial Research. Certain of the technical and industrial organizations concerned in the subject would also send representatives.

#### Notes in Brief.

On April 3rd Sir P. CUNLIFFE-LISTER told Lieutenant Commander Kenworthy that the inspection of crew spaces on British merchant vessels was one of the duties of the Board of Trade survey staff, which numbered 198 in all. Any defects discovered were notified to the owner or agent, with an intimation that if the defects were not remedied the space would have to be added to the tonnage of the ship, and that this procedure had the desired effect. It had been his experience that wherever defects had been brought to the notice of shipowners practically in every case they had been attended to.

The total amount of the invested funds of approved societies in connexion with the National Health Insurance Act at December 31st, 1927, was approximately £111,000,000.

## The Services.

### TERRITORIAL MEDICAL DINNER.

A REUNION DINNER, open to all past and present Territorial medical officers, including *à la suite* officers, will take place, under the auspices of the Territorial Army Medical Association, on May 11th, at 7.30 p.m., at the Connaught Rooms, Great Queen Street, W.C.2, with Major-General Sir Richard H. Luce, K.C.M.G., C.B., M.P., in the chair. Price of dinner, 12s., exclusive of wine. For tickets application should be made to the Secretary, Territorial Army Medical Officers Association, 36, Russell Square, W.C.1.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

THE Electors have awarded the George Herbert Hunt Travelling Scholarship, 1928, to Thomas Holmes Sellers, B.M., Oriel College, casualty surgical officer at the Middlesex Hospital.

At a congregation held on March 31st the following medical degrees were conferred:

B.M.—D. H. Brinton, Oliver H. Lister.

### UNIVERSITY OF DURHAM.

THE following candidates have been approved at the examination indicated:

THOMAS M.B., B.S.—Pathology and Bacteriology; *Materia Medica, Pharmacology, and Pharmacy; Public Health; Medical Jurisprudence*; H. U. G. Harrison. Pathology and Bacteriology, *Materia Medica, Pharmacology, General Principles of Therapeutics, and Pharmacy; Public Health; Medical Jurisprudence*: A. R. D. Pattison, J. C. Arthur, M.Sc., A. Franklin, S. Adler, W. F. Cross, K. Daniels, A. Davis, S. M. Garstela, C. M. Gillis, Katherine M. Girling, C. E. Goldberg, R. W. T. Hall, J. G. Lawson, J. A. Lennox, D. C. Livingston, J. Maddison, W. Muir, J. H. Pool, J. K. H. Scott, J. W. M. Stevenson, J. B. Tilley, H. Wilcox, J. Wolfe.

\* First-class honours. † Second-class honours.

### ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN ordinary committee of the Royal College of Physicians was held at 5 p.m. on April 2nd.

The President, Sir John Rose Bradford, gave the annual presidential address and reviewed the work of the College. The number of Fellows was 385 and of members 916. Gifts of the portraits of past Fellows (Sir James Hople and Sir Percy Bassett-Smith) had been received. The President gave an account of the life and work of the following Fellows who had died during the year: Ernest Henry Starling, Henry Cook, Sir Horatio Bryan Donkin, Charles Wilberforce Daniels, Alexander Blackhall Morison, Amand Jules McConnell Ronth, Sir Percy William Bassett-Smith, Sir Dyce Duckworth, Sir Dawson Williams, Sir David Ferrier, Hugh James Moore Playfair, Henry Lawrence McKisack, and William Joseph Tyson.

Sir John Rose Bradford was re-elected President for the ensuing year.

The resignation of Sir Wilmot Heringham as representative of the College on the Senate of the University of London was accepted with much regret. It was decided not to fill the vacancy, as the new Senate of the University would shortly be appointed and the College would not be represented on it. The President was appointed as delegate to the commemoration of Harvey's discovery by the Academy of Medicine in Paris.

Mr. Vernon Joseph de Boissiere was declared to be no longer a Licentiate of the College, having been convicted in the High Court (Divorce Division) of adultery with a patient.

#### Diplomas.

The Diploma in Tropical Medicine and Hygiene was granted to the following forty-four candidates:

C. R. Amies, Mary N. Andrews, R. A. Dunlop, H. Fairbairn, M. M. Fikri, O. M. Francis, W. J. C. P. Grey, Alma B. Har, D. R. Jandial, B. M. Johns, R. S. Johnston, F. B. Jones, Margaret E. Lovett, Margaret M. McDowall, A. A. E. M. Magraby, R. C. Mahajan, M. V. Merchant, J. C. Milne, J. H. Oonvala, T. Parakkutti Ammal, J. R. Pierre, E. W. Rooco, J. D. Reynolds, Enid A. Robertson, G. I. Shaw, T. A. Sherwin, G. Sloan, Hilda M. Smith, A. E. M. Soliman, Grace M. L. Smmmerlayes, V. E. Whitman, N. J. Williams, C. H. Williams, H. M. Willoughby.

## Medical News.

THE KING has appointed Mr. Laurence George Brock, C.B., to be a Commissioner under the Mental Deficiency Act, 1913, to fill the vacancy caused by the retirement of Sir Frederick Willis.

THE next meeting of the Harveian Society of London will be held on Thursday, April 19th, at the Paddington Town Hall, at 8.30 p.m., when there will be a discussion on the treatment of ulcerative colitis from medical and surgical points of view. It will be opened by Dr. H. Letheby Tidy, followed by Mr. L. E. C. Norbury, Dr. E. Bellingham Smith, and Mr. C. P. G. Wakeley.

A MEETING of the Society of Medical Officers of Health will be held at the Guildhall, Bath, on April 20th, at 2.30 p.m., when there will be a discussion on causes of the decline in tuberculosis mortality. The opening speakers will be Sir Robert Philip, Dr. W. M. Willoughby, Professor E. L. Collis, and Professor M. Greenwood. Before the meeting the Mayor of Bath will entertain members of the society at luncheon. Those who intend to be present are asked to notify Dr. J. F. Blackett, M.O.H., Health Offices, Sawclose, Bath, not later than April 16th.

THE following additional appointments have been made to the staff of the Woolwich War Memorial Hospital: Obstetric surgeon, Mr. Harold Taylor, F.R.C.S.; senior anaesthetist, Dr. de Caux; anaesthetists, Dr. Moore Smith and Dr. Dyson. Dr. Cowie and Dr. Moore Smith have been elected to the medical committee of the hospital to represent the interests of the practitioners in the Woolwich district.

THE Health Organization of the League of Nations, following the policy adopted since 1926, has arranged a series of special study courses for medical practitioners who have specialized or who desire to specialize in malaria. Courses will be held this year in London from April 25th to June 13th, in Hamburg from May 7th to June 13th, in Paris from June 1st to July 13th, and in Rome from July 2nd to July 30th, the instruction being given in each case in the language of the country concerned. Details may be obtained from the Information Section of the League of Nations, 16, Northumberland Avenue, W.C.2.

FOLLOWING the establishment of an orthopaedic branch by the Melbourne Children's Hospital the committee is inviting applications for the position of medical superintendent; details will be found in our advertisement columns. A small experimental ward for orthopaedic work has been in existence for about two years, and its success has led the committee to undertake a larger scheme. The new buildings now in course of erection on a spacious site at Frankston, on the sea coast twenty-six miles from Melbourne, will have accommodation for 100 patients, provision being made for physiotherapy, hydrotherapy, and occupational therapy departments, a gymnasium, and school rooms. All the wards will be entirely open on one side to facilitate heliotherapy. It is expected that the new hospital will be ready for occupation about May, 1929.

A SOCIETY with the name of the London Jewish Hospital Medical Society has been constituted, with its headquarters at the London Jewish Hospital, Stepney Green, E.1.

THE KING has confirmed the appointment of Dr. Kenrick Stanton Wise (Surgeon General) to be an official member of the Legislative Council of Trinidad and Tobago, and of Dr. Arthur Hutton McShine to be an unofficial member.

Health and Empire, the journal of the British Social Hygiene Council, has embarked on its third year with the March number, published by Messrs. Constable and Co., at 2s. 6d. An editorial note explains that the council is anxious to extend the circulation of the journal, and the current issue includes material in easily understandable form intended for parents and others concerned with the education of youth.

THE League of Nations announces the publication of the *International Health Year-book, 1927*, the third annual volume, which contains reports on public health in twenty-seven countries in 1926. These countries include the leading member-States of the League, the United States of America, and the Soviet Republics. The first three sections of the work deal with demography, budgets, and health legislation respectively; the fourth is devoted to the preventive aspect of medicine, the fifth to its therapeutic side, and the sixth to general questions, such as the control of foodstuffs, water supply, and health insurance. Copies may be obtained from the League of Nations Publications Department, Geneva, the price being 16s. in paper wrappers, or 20s. in cloth.

A chair of tuberculosis, founded by the Conseil Général de la Seine, has just been established at the Faculté de Médecine of Paris, and Professor Léon Bernard has been appointed as its first occupant.

# A British Medical Association Lecture ON PRACTICAL APPLICATIONS OF RECENT VIEWS ON THE MENSTRUAL FUNCTION.

GIVEN TO THE SHEFFIELD DIVISION, DECEMBER 9TH, 1927,  
BY

BECKWITH WHITEHOUSE, M.S., F.R.C.S.,  
PROFESSOR OF GYNAECOLOGY AND ORSTETRICS, UNIVERSITY OF  
BIRMINGHAM; GYNAECOLOGICAL SURGEON, GENERAL HOSPITAL,  
BIRMINGHAM; SURGEON, BIRMINGHAM MATERNITY HOSPITAL.

STRANGE beliefs about menstruation are very widespread, and this element of mystery seems, as Novak says, "to have inhibited intelligent efforts to study." It was taken for granted that the function was essentially a cleansing process, its purpose being to cleanse the blood of various impurities, a view still held to-day by not a few lay members of the community. One of the important practical applications of recent views on the menstrual function is the sweeping away of this atmosphere of superstition and speculation. During the last few years what may be described as a new "sexual physiology" has been written, and facts have come to light which prove that the human species in essential details shows but a variation of sex phenomena common to other members of the mammalian family—a variation designed to secure the maximum reproductive activity. This knowledge in due course must produce in the lay mind a more natural atmosphere with regard to everyday ideas about the menstrual function. When menstruation ceases during the years of active sexual life a woman, if not pregnant, still commonly believes herself to be retaining some noxious principle to the detriment of her health. Also many members of our own profession still regard the menstrual function as being nothing more than a preparation for pregnancy.

I need not describe at length the observations and experiments which have led to the modern conclusion that, in the human species, menstruation is a composite function involving two distinct factors. It is necessary, however, to state briefly the nature of the essential factors, as otherwise much of what follows may be difficult to comprehend.

## The Oestrous Cycle.

The time when physiological activity of the reproductive system occurs in mammals is called the sexual season, and during this period a series of cyclical phenomena take place known as "oestrous cycles." Each cycle is physiologically divided into four separate phases:

1. A period of sexual rest (amenorrhoea).
2. A period of growth and functional activity of the sexual organs (pro-oestrus).
3. A period of "heat," when fertilization is effected (oestrus).
4. A period of pregnancy or "pseudo-pregnancy" (met-oestrus).

Considerable variation occurs in different species with regard to the presence, absence, and duration of each of these various subsections of the oestrous cycle, and also with regard to the number of complete oestrous cycles in each sexual season. Breeding, artificial selection, and luxurious conditions can and do introduce great variation into the sexual cycles of most animals—a fact commonly utilized in certain breeds of domestic animals.

Haemorrhage from the genital tract in the case of different species occurs at two points of the oestrous cycle. In some, as the bitch, slight bleeding from the uterus is seen at the end of pro-oestrus due to extreme local hyperaemia of the sexual organs. In other types, as the cow, haemorrhage only occurs at the end of the pseudo-pregnancy, from necrosis and expulsion of a false decidua. In yet other animals—for example, sheep, mare, sow, and various rodents—no haemorrhage into the uterine cavity occurs at all, either during the stage of pro-oestrus congestion or during involution at the end of pseudo-pregnancy.

## Menstruation in the Human Female.

In the human female ovulation occurs from the thirteenth to the seventeenth days of the menstrual cycle, and from this point a state of pseudo-pregnancy exists until its

termination about the twenty-eighth day. Necrosis of the menstrual endometrium, or "decidua" as it should be called, then takes place and external haemorrhage begins. *Pari passu* with the completion of the pseudo-pregnancy a state of pro-oestrus develops, which also reaches its acme about the twenty-eighth day of the cycle, and persists during the expulsion or abortion of the pseudo-pregnancy. This is followed at the conclusion of the menstrual haemorrhage by a short oestral period—Nature's provision to promote fertilization of the next ovum to be liberated from a maturing Graafian follicle.

The menstrual discharge in the human species, therefore, normally contains blood as a result of two distinct factors—namely, that resulting from necrosis and abortion of the pseudo-pregnant decidua, and that due to pro-oestral hyperaemia. The blood is mixed with the secretion of the uterine glands liberated as the result of necrosis of the superficial or compact layer of the menstrual decidua. In all mammals activity of the uterine glands is a prominent feature of pro-oestrus, and the human species is no exception to the rule. The glands of the body and the cervix probably have, however, a very different function. The secretion of the corporeal glands is poured out only after necrosis of the endometrium has occurred. It contains excess of calcium, a ferment or "thrombolytin" which dissolves blood-clot, and apparently also a hormone which stimulates oestrus. The cervical glands, on the other hand, only produce mucus, and probably their function is to facilitate the passage of products from the corpus uteri to the vagina.

The glandular activity of the endometrium during the pro-oestral state is a very interesting phenomenon. It is more than possible that the high calcium content of the secretion is a provision of Nature for the needs of the developing ovum should fertilization occur, as is the case with the so-called "mare's milk" of ungulates. The other great function of the secretion is to dissolve and clear away the products of the unfertilized abortion or unwanted decidua if fertilization is not effected. This fact has a practical application to which I shall refer presently in connexion with the cause of menstrual pain. In the light of recent work upon ovulation and the corpus luteum, menstruation must be regarded as representing primarily the end of a pseudo-pregnant state resulting from the preceding ovulation. The unfertilized abortion is in addition complicated, and in a sense masked, by the very evident glandular activity, oedema, and hyperaemia of pro-oestrus, superimposed upon the primary phenomena in readiness for the next ovulation.

It is a provision of Nature to waste no time. Not only is anoestrus or the "rest" period in the human species completely abolished, but while the remains of the previous debacle are being cleared away the stage is being set for the next scene, which Nature trusts may be more successful. Appreciation of the fact that menstruation involves two functions in the sexual cycle, each serving a definite physiological process, but overlapping the other, throws light upon what otherwise is a difficult problem.

## "Oestrin" and "Ovarin."

The menstrual function has been studied during recent years from both these points of view. During the last twelve months references to the ovarian hormones, particularly the so-called "oestrin," have frequently appeared in the medical press. Now the recognition, isolation, and investigation of the physiological properties of oestrin is research associated with the pro-oestral and oestral factors of the sexual cycle. On the other hand, the clinical and experimental observations resulting from destruction or removal of the Graafian follicle or corpus luteum are concerned with the pseudo-pregnant aspect of menstruation.

The cause of pro-oestrus and oestrus is undoubtedly an accumulation in the tissues of the hormone oestrin demonstrated by Allen and Doisy in America and by Dickens, Dodds, and Wright in this country. This oestrus-producing hormone, although present in the liquor folliculi, is not confined to the follicle. It has also been demonstrated in ovarian tissue without follicles, in the human placenta, and in the secretion and tissues of the uterus. It has not, however, been found in the corpus luteum, and,

according to the recent experiments of A. S. Parkes, its production is also independent of ovarian follicular activity.

At the present time there appears to be rather a widespread opinion that the oestrus-producing hormone is all-important in the production of menstruation in the human species. Personally I am not prepared to admit that it is more than one factor. Oestrin will cause hyperaemia, development, and glandular activity of the uterus, but there is no evidence to show that it produces growth of the endometrial stroma which, when completed, constitutes the decidua. Decidual development requires the constant stimulus of another hormone of the ovary—"ovarin," present in both Graafian follicle and corpus luteum. Oestrin cannot be demonstrated in the corpus luteum, and yet, when this body is excised, necrosis of the endometrium with haemorrhage always occurs. It terminates the pseudo-pregnant state.

An interesting series of observations carried out in my department showed not only that destruction of the corpus luteum results in necrosis of the endometrium in from forty-eight to seventy-two hours, but that similar trauma to ripening Graafian follicles also produces a like effect. In other words, the integrity and development of the endometrium require the constant supply in the circulating blood of a hormone other than oestrin, and elaborated in both follicles and corpus luteum. If this supply is cut off for any reason, then the endometrium necroses at whatever stage of development it may be. The fact that menstruation occurs with necrosis of the endometrium within a few hours of excision of the corpus luteum appears to provide indisputable evidence of the independence of ovarin and oestrin. Both hormones are important for the economy of the individual and the maintenance of the species, but each serves a separate function.

The essential points, therefore, in the theory of menstruation which I am setting out are these: The menstrual function in the human female represents two things—

- (1) The abortion of a useless decidua of the pseudo-pregnancy corresponding to the preceding ovulation.
- (2) The acme of pro-oestrus to promote fertilization at the succeeding ovulation.

The abortion is the result of cutting off the supply of ovarin through death of the ovum and its corpus luteum. Pro-oestrus is caused by accumulation in the tissues and uterine glands of oestrin.

These views receive a practical application when the various pathological conditions associated with the menstrual function are considered. In view of the complexity of the function it is not surprising that anomalies of it are common; indeed, it would be strange were it not so. The establishment and regularity of the normal menstrual rhythm in health from puberty to the menopause is a very remarkable phenomenon, and when we take into consideration the changes in the sexual cycle which can artificially be produced in other members of the mammalian family by such factors as changed environment and feeding, it is only to be expected that the complications and complexities introduced by evolution and civilization will be reflected in variation from type.

#### "White Menstruation."

Such variation usually proceeds along progressive lines, but occasionally phenomena that are atavistic or reversionary are seen in the human species. It is important to remember that atavism can occur with regard to physiological function just as it does with anatomical structure. Two or three examples will make the point clear. The first is the phenomenon known as "white menstruation." Individuals are occasionally seen in whom the menstrual function is never exhibited on normal lines, in that no haemorrhage occurs, although the conformation and structure of the sexual organs present no abnormality. Such women experience the usual menstrual moulting attributable to the onset of the "negative phase" and the development of pro-oestrus; but the subsequent discharge consists of the secretion of the uterine glands only. There is no endometrial necrosis and no external haemorrhage. For in parallel we must study the sex cycle of a polyoestrous mammal such as the merino sheep, where the end of pseudo-pregnancy is not accompanied by tissue necrosis.

Minor degrees of the same atavistic type are not so uncommon. In these subjects the menstrual haemorrhage is very slight and may only be present for a few hours. On the other hand, the periods may be separated by what are apparently long intervals of amenorrhoea. Patients of this type commonly also suffer from severe menstrual pain caused by defective physiological function of the uterine secretion.

The important practical point is that ovulation is normal and therefore fertility is not impaired. Hence it is unwise ever to express an opinion upon the possibility of pregnancy in cases of apparent amenorrhoea without first making a very careful physical examination.

#### "Vicarious Menstruation."

Another interesting anomaly of somewhat similar type is the so-called "vicarious menstruation." The explanation of these interesting cases probably lies in an abnormal and excessive pro-oestral hyperaemia, associated with atavistic absence of endometrial necrosis. A parallel can be found in the corneal haemorrhage which occurs during the pro-oestrus of some rodents. On two occasions I have known haematemesis occur during the pro-oestral state of the domestic cat.

Another explanation of vicarious menstruation is an unbalanced action between the pseudo-pregnant abortion and the pro-oestral state. The local congestion and general vaso-dilatation produced by the activities of oestrin are normally relieved by the haemorrhage which ensues when the pseudo-pregnancy ends. If for various reasons, atavistic or otherwise, this physiological necrosis does not take place, the congestion is likely to be relieved by haemorrhage from other mucous surfaces. There is, I think, very little doubt that, although both factors of the menstrual phenomenon usually coincide, either may be suppressed independently of the other. If, for example, ovulation is defective, pseudo-pregnancy does not occur and the individual, incidentally, is sterile. On the other hand, oestrin may be produced in normal or even excessive amount, giving rise to an exaggerated pro-oestral state. In some cases of hyperthyroidism there is evidence of excessive oestral activity; but this by no means always coincides with increased fertility or even increased menstrual loss. In exophthalmic goitre, during the early stages, we know that menorrhagia is the rule, and can be explained by excessive pro-oestral congestion superimposed upon the menstrual abortion. In the later stages ovulation is suppressed, and although pro-oestrus and oestrus are often marked, amenorrhoea is commonly present.

When ovulation occurs without the development of oestrus, menstruation is rather scanty, but fertility is unimpaired. Such individuals are the subjects of sexual frigidity, and commonly dysmenorrhoea also.

The third and last example of atavism to which I shall call attention is the occasional passage of a large solid menstrual "clot" as the sole manifestation of the menstrual function. This phenomenon, which is normal in the case of some monkeys, is sometimes seen in the human species. I met with an example some years ago in the case of a girl of 19 who, from the age of 16, regularly at each period voided a solid rounded clot, which superficially resembled an early abortion. It was passed apparently without pain and was unaccompanied by any other discharge. I recently heard that this patient is now married and has been pregnant. It was interesting to note that after marriage the menstrual discharge assumed the normal character and no more clots were noticed.

#### Abnormal Uterine Haemorrhage.

The variations of the menstrual function which come most frequently under our notice are those concerned either with excessive or irregular haemorrhage, or with intense pain.

For many years we have been accustomed to group our cases of pathological uterine haemorrhage under one or two headings—namely, "menorrhagia" and "metrorrhagia." In the early days of gynaecological physiology and pathology this simple classification served a useful clinical purpose. It was undoubtedly crude and based upon clinical phenomena only, but it sufficed for the time. As knowledge

increased a revised nomenclature has gradually been evolved, and new terms have been introduced to denote the various clinical types of pathological haemorrhage.

Critically speaking, abnormal bleeding falls naturally into one of four groups: the menstrual "periods" are too frequent (epimenorrhoea), or they are too severe as measured by the blood lost (menorrhagia), or they are too prolonged (menostaxis), or the haemorrhage is quite irregular (metrostaxis).

Too frequent menstruation, or "epimenorrhoea," is the clinical manifestation of abnormal ovulation. The normal rhythm is, of course, an index of ovarian function in terms of follicular activity. Epimenorrhoea is commonly associated with ova of low vitality, and therefore is frequently combined with sterility. Not infrequently it is also a clinical symptom of abnormal bodily metabolism. Sterility without physical signs is often associated with a low basal metabolic ratio, and, if combined with epimenorrhoea, the basal metabolic ratio should be estimated. If reduced, improvement in the general bodily health and the administration of thyroid extract may remedy both conditions.

Care must be taken not to confuse epimenorrhoea with irregular uterine haemorrhage or metrostaxis. Any haemorrhage from the genital tract is commonly regarded by a woman as being a menstrual "period," normal or otherwise. When there is an apparent rhythm established, even with abnormal bleeding, a patient naturally comes to the conclusion that her "periods" are too frequent, and she expresses herself in these terms.

Now there are two periods of life when epimenorrhoea is common—so common, in fact, as almost to be physiological. One is at puberty and the other is at the menopause. At both these epochs a state of ovarian instability exists. At puberty the sexual organs have reached functional activity, due most probably to the development and repeated stimulation of oestrin. At the menopause a state of sexual instability exists owing to exhaustion of the supply of one or both of the ovarian hormones. It is interesting to observe, however, that the sexual instinct is often developed before puberty and, of course, commonly persists for many years after the menopause, pointing to the independence of the oestral phenomena in the menstrual function. At both puberty and the menopause, however, there is one factor in common—namely, the presence in the ovaries of ova of low vitality. In the one case it is due to immaturity, in the other to sexual old age. The occurrence of these ova of low vitality, observed in many animals, is, I believe, intimately associated with, and probably the cause of, the epimenorrhoea and metrostaxis of puberty and the menopause.

#### *Relation of Follicular and Lutein Cysts and Haematomata to Uterine Haemorrhage.*

I have already said that experimental destruction of maturing Graafian follicles produces necrosis of the developing endometrium. Now if such necrosis and haemorrhage can be produced by trauma it is reasonable to suppose that a similar condition of the endometrium will result from death of the Graafian follicle and cessation of its physiological activity. In ovaries that are examined both at puberty and the menopause, from patients in whom epimenorrhoea is a prominent symptom requiring treatment, evidence of abnormal ovulation is frequent. Such ovaries as I have examined contain many cystic follicles in which the epithelium is wanting; or haemorrhage has occurred leading to the production of follicular haematomata. Certain gross pathological conditions in which irregular menstruation is a common symptom—for example, uterine fibromyomata, backward displacements of the uterus, and pelvic inflammation of a chronic nature—commonly exhibit similar lesions in the ovaries. The abnormal haemorrhage and the sterility, which are often combined in these cases and which have previously been attributed to some hypothetical lesion, such as a coexisting "endometritis," owe their common origin to the presence of these dead follicles. The defective ovulation which initiates the train of events is not unlikely the result of circulatory changes in the ovaries produced by the pathological lesion present.

If this conception is correct—and there is certainly a considerable weight of clinical and pathological evidence to support it—the uterus is to be regarded only as the mirror of abnormal ovarian activity. In the past, I am afraid, it has suffered many assaults from being in bad company!

An important practical application based upon the connexion between abnormal ovulation and uterine haemorrhage is the position which ovarian surgery will occupy in the future in the therapy of uterine bleeding. The cystic ovary, or the ovary which contains haematomata, assumes a new importance in the light of these facts. Double oöphorectomy has, of course, long been condemned, but partial oöphorectomy, by removing diseased follicles or pathological corpora lutea, may well prove to be a useful application. Cystic follicles increase intraovarian tension and so interfere with subsequent ovulation. A vicious circle is indeed set up which tends to perpetuate irregular uterine bleeding and sterility. Follicular haematomata can be artificially produced in certain animals—for example, the cat—by the prevention of pregnancy through coitus with a vasectomized male. It seems possible, therefore, that anticonceptual measures in the human species may be followed by a like occurrence, and that the irregular menstruation which sometimes accompanies the practice has its explanation in this manner.

The circulation in the ovary is without doubt a very important factor in normal ovulation. When it is altered as the result of surgical trauma, prolapse of the ovary, the development of uterine or ovarian neoplasms, or pressure from inflammatory adhesions, ovulation is defective, and this is reflected clinically in the occurrence of irregular and protracted uterine bleeding. During operations upon the Fallopian tubes the greatest care should therefore be exercised not to interfere with the ovarian circulation. Furthermore, in the course of myomectomy for uterine fibromyomata, the ovaries should always be inspected and diseased follicles or corpora lutea excised.

A backward displacement of the uterus is always more serious if the ovaries are also prolapsed and their circulation affected. In fact, the existence of irregular uterine bleeding in association with a retroverted uterus may almost certainly be considered to be due to defective ovulation and the presence in the ovaries of pathological follicles. If this symptom is present there is a clear indication for surgical intervention—for example, ovarian suspension.

#### *Ovarian Grafting.*

Another practical application of somewhat similar nature is concerned with the value of ovarian grafts. Ovarian grafting is advocated in certain conditions, such as pelvic inflammatory disease, which involve the separation of both ovaries from their normal attachments, upon the assumption that the maintenance of the menstrual function is essential to the well-being of the individual.

Now if such a graft produces only follicles which reach a certain stage of maturity and then die, the resulting endometrial necrosis and accompanying uterine haemorrhage which represent the "menstrual period" are clearly only phenomena of doubtful value, beyond conferring a possible psychological benefit. Menstrual haemorrhage as such is not an essential to the body economy and well-being, beyond the fact that it may relieve the local and general congestion produced by the action of oestrin. The vasomotor "flushes" of the menopause appear to be caused by the unbalanced action of oestrin without local depletion. Sexual life is not commonly affected by total ablation of the ovaries, and there is therefore no necessity to graft ovarian tissue with the idea of conserving oestrins. There thus remains only the metabolic factor upon which to base the *raison d'être* of ovarian grafting. Since evidence is available which tends to prove that the cells of the ovarian stroma are responsible for the hormone which is an integral part of the "sex complex," it appears reasonable to suggest that only this tissue should be employed for the purpose of grafting. To insert deliberately into the tissues Graafian follicles, which in all probability will necrose before maturation owing to circulatory deficiencies, is to confer upon the patient a

## An Address

ON

## RINGWORM AND ITS TREATMENT.

DELIVERED BEFORE THE HENDON DIVISION OF THE BRITISH  
MEDICAL ASSOCIATION

BY

J. M. H. MACLEOD, M.D., F.R.C.P.,

PHYSICIAN FOR DISEASES OF THE SKIN, CHARING CROSS HOSPITAL;  
CONSULTANT PHYSICIAN FOR DISEASES OF THE SKIN,  
METROPOLITAN ASYLUMS BOARD.

## INTRODUCTORY.

In selecting ringworm as the subject for this lecture, which your Division has so greatly honoured me by asking me to deliver, I have been guided in my choice by experience that the recognition of ringworm is liable to prove a stumbling block to the practitioner, and that the difficulties of its successful treatment are apt to be so great as to render it almost a subject of reproach by the laity.

Ringworm is a common affection of the skin, due to a group of mould fungi, which may attack the glabrous skin, hairs, nails, and in rare instances, by extension, the mucous membranes, the clinical appearances of which differ according to the variety of fungus responsible, the site of the lesions, and the individual peculiarities of the skin affected.

## RINGWORM FUNGI.

The fungi, or hyphomycetes, of ringworm constitute an interesting group, which has been placed provisionally in the order of the Ascomycetes, and in the family of the Gymnosaceae. In the skin they grow anaerobically in the form of a network of mycelial threads or "hyphae," which constitute the vegetative part of the fungus. The hyphae break up into small sections, to which the name "spores" has been applied, which in turn become elongated into new hyphae, and so perpetuate the fungus. Other methods of reproduction occur if the fungus be grown anaerobically away from the skin. In culture, for example, reproduction takes place by chlamydo-spores, while in hanging drop preparations it takes place by endoconidia. Its true method of reproduction, however, is aerobic, when it proliferates by means of aerial hyphae with terminal and lateral buds.

For many years it has been known that ringworm is due to a number of different fungi, which are so closely allied and so similar in their microscopical appearances as to be almost indistinguishable, but are capable of differentiation by cultivation on certain artificial media. Certain of them are found only on the human skin, while a considerable number occur in lower animals, and in birds, from which they are transmissible to man. The fungi are transmitted directly by contact, or indirectly by infected combs, brushes, caps, clothes, bath mats, etc. It is even possible that the infection may take place by spores blown about in the atmosphere, as dried spores have been shown to be viable for more than a year, and might easily remain about rooms where infected persons had been.

## Pathogenic Action.

The fungi of ringworm have a double action on the skin: (1) a corrosive action on the epidermis, hairs, and nails, owing to the elimination by the fungus of a keratolytic ferment; and (2) an irritant action from their rapid growth and the toxic influence of the ferment, which results in inflammatory reactions, varying in degree from mild erythema to vesico-pustular or even granulomatous lesions. The degree of inflammation is dependent on the variety of the fungus—those of animal origin being specially virulent—and the susceptibility of the individual skin, which may be a natural peculiarity, or acquired as the result of some constitutional disturbance. As an example of the latter happening, I recently had a case of ringworm of the scalp in a child, in which the lesions were of the dry, scaly, slightly inflamed type; an attack of measles supervened, and the patches of ringworm became acutely inflamed, raised, and dotted over with vesico-pustules.

## Varieties of Fungi.

There are two main groups of ringworm fungi, known respectively as the Microspora and the Trichophyta.

1. *Microspora*.—In Great Britain there are four varieties of microspora which are of practical importance—namely, the *M. audouinii* (Gruby, 1843), *M. caninum vel lanosum* (Bodin), *M. felinum* (Colcott Fox and Blaxall). Of these the *M. audouinii* is by far the most common, and is responsible for at least 90 per cent. of all cases of ringworm of the scalp, and for a large number of those of the glabrous skin. It is a human ringworm, while the other three, as their names indicate, are of animal origin. It attacks the scalp in children, but rarely the adult scalp, as at puberty, for some reason so far unexplained, the scalp becomes an unsuitable soil for its growth, and, consequently, scalp ringworm in children, due to this fungus, tends to disappear spontaneously about the age of 14 years.

2. *Trichophyta*.—There are two main varieties of trichophyta which attack the human skin—namely (a) the *T. endothricae*, which are of human origin, and (b) the *T. ceto-endothricae*, which are transmitted from animals.

(a) In this country there are three principal varieties of *T. endothrix*, which are distinguished by presenting distinctive colours when grown on prop agar in the dark—namely: (1) *T. crateriforme*, a cream-coloured culture; (2) *T. sulphureum*, a yellow crateriform culture; and (3) *T. acuminatum*, a greyish-yellow acuminate culture.

(b) The *T. ceto-endothricae* form the largest group of the ringworm fungi, and most of them are of animal origin. They are responsible for the majority of cases of ringworm in adults. Of these the most common are: the *T. nircum* of cats and dogs; *T. equinum* of horses, sometimes found in the beard in man; *T. rosaceum* of fowls, in which it gives rise to the disease known as "white crest"; and *T. violaceum*, which has been recovered from suppurative ringworm of the beard, face, and scalp.

In addition there are several varieties of trichophyta of human origin, to which the name Epidermophyta has been given, such as the *E. inguinale* (Sahourand) and *E. rubrum* (Castellani). These are mainly responsible for ringworm of the crutch and axillae, and the eczematoid ringworm of the feet and hands.

## CLINICAL APPEARANCES.

## Glabrous Skin.

Any part of the glabrous skin may be attacked by ringworm, the lesions varying according to the fungus responsible and the type of skin affected. They may be scaly macules, irregular, ringed, or gyrate in shape, vesico-pustular patches, or occasionally granulomatous nodules, the more virulent lesions being usually of animal origin.

The intertriginous regions—namely, the crutch, axillae, beneath the breasts in stout women, and the interdigital spaces between the fingers and toes—may be the sites of a special variety of ringworm, which has been known variously as *tinca eruris*, *dhobie's itch*, or *eczematoid ringworm*. This variety, which came originally from the East, has increased enormously since the great war, as large numbers of the troops campaigning in the East were infected with it, brought it home, and spread it among the civil population. Its exact manner of transmission is uncertain, but it is probably most often conveyed indirectly by walking barefoot on infected floors, by bath mats, water-closet seats, etc. It is possible that in some cases the strong belief in India that the *dhobie*, or washerman, is responsible for its spread, by washing clothes in pools of stagnant, infected water, may not be ill founded. The objectionable habit of wearing trousers next the skin is a likely way of keeping up the infection, and in public schools it has been traced to boys wearing promiscuously one another's football shorts, or other garments.

In the crutch and axillae it gives rise to irregular patches with a well-defined, sometimes festooned, border, which may be scaly, or raised and dotted over with oozing papules or vesico-pustules—hence its old name "*eczema marginatum*" (Hebra).

On the feet and hands it occurs in three main types. (1) An aceto vesico-bullous type, generally known as

"eczematoid ringworm of the extremities," which attacks the interdigital clefts, and may spread on to the dorsum of the foot or the back of the hand in erythematous patches, which may be scaly, or dotted over with vesico-pustules, or may present a sharp edge, with detached, undermined skin. This type is often mistaken for acute eczema, and many cases formerly labelled dysidrosis belong to this category. (2) A chronic type, which may succeed the acute type, characterized by indefinite, scaly patches. (3) A thick scaly type, affecting the palms and soles, in which the horny layer is not only thickened but fissured. These patches are irregular in shape, with detached edges, beyond which may be an erythematous areola, and small vesico-pustules. Between the toes, especially between the fourth and fifth toes, the skin is apt to become white and sodden, like suede leather, and fissured in the folds. The nails may also be implicated, becoming discoloured, thickened, brittle, and raised up at the free border, owing to a thickening of the nail-bed. Subjective symptoms are not infrequent in connexion with it—such as itching, discomfort, and even pain from fissures, which may be so great as to interfere with walking.

The diagnosis of eczematoid ringworm may present great difficulty. In the extremities it has to be distinguished from "dysidrotic eczema," or even in some cases from a late syphilide, and cases are not infrequent which have been treated as eczema for years before their true nature was recognized. In doubtful cases a microscopical examination should always be made. With this object a scale should be detached at the growing edge of the lesion, or a covering of a vesicle removed, and placed with the deep side uppermost on a microscopical slide. A drop of liquor potassae should be added, a cover-slip applied, and the specimen examined with a high power. It may be necessary to make several preparations before a positive result is obtained, when the fungus can be detected as a network of mycelial threads among the epidermal cells.

#### Scalp.

The clinical appearances of ringworm of the scalp may be conveniently considered under three headings: (1) suppurative ringworm; (2) microsporon ringworm; and (3) endothrix ringworm.

1. *Suppurative Ringworm.*—Suppurative ringworms of the scalp are known as kerions, and are generally due to trichophytha of animal origin, though occasionally in children they may be caused by microspora. They may occur at any age, and constitute the majority of ringworms of the adult scalp. The lesions are boggy, phlegmonous raised patches, with a shiny, angry-looking surface, and a well-defined border, and are usually dotted over with small peri-follicular abscesses, from which ooze beads of sero-pus, and in the centre of which a loose stump may often be detected. On palpation they have a peculiar soft, fluctuating feeling, which leads the inexperienced to incise them in the expectation of finding pus, instead of which only a few drops of blood or serum exude. The suppuration is due to the inflammatory reaction of the scalp to the fungus itself, and not to a secondary infection with pus-coeci.

2. *Microsporon Ringworm.*—The microsporon is responsible for the familiar, mildly inflamed, scaly patches in children, in which the hairs are broken off short and form the characteristic ringworm stumps. In the infant, where the hairs are delicate, the patches may be definitely ringed, but in older children they are usually irregular in shape. The stumps are easily recognized, being thicker than the healthy hairs, and presenting a dirty white, opaque, or frosted appearance, due to a sheath of fungus around them. Recently a useful aid to the diagnosis has been furnished by the ultra-violet rays through a Wood's glass screen, as ringworm stumps become fluorescent under this light, and by this means not only patches of ringworm, but isolated infected hairs can be detected. As a rule the inflammation in this type of ringworm is mild, but occasionally, owing to some peculiarity of the scalp, on account of which it reacts more powerfully to the fungus, it may be so severe as to go on to suppuration. Should this happen, it is to the advantage of the patient, as the ringworm becomes self-curative.

3. *Endothrix Ringworm.*—Endothrix fungi are responsible for about 5 per cent. of the cases of scalp ringworm. The characteristic lesions produced by them are small, scaly, roundish patches, irregularly distributed over the scalp. In certain cases short stumps are present, but more often the affected hairs are broken off at the orifices of the follicles, forming plugs like comedones; hence the name "black-dot ringworm." These plugs are difficult to remove, except by a comedo expressor, or by detaching a scale covering an affected follicle, when the plug appears as a small spike on the under surface. Endothrix ringworm is generally of human origin. It is difficult to diagnose on account of the smallness of the patches and the shortness of the stumps, and is often mistaken for tinea, as the fungus has no tendency to spread at puberty.

#### TREATMENT.

Ringworm, being a local affection, is not amenable to any form of internal treatment. A number of experiments have been performed in connexion with the production of immunity to it in man and animals by the injection of vaccines, but these have only been partially successful in the case of suppurative ringworm of animal origin, and have not helped materially in the treatment of the disease.

#### Glabrous Skin.

The treatment of ringworm of the glabrous skin is as a rule a simple matter compared with that of the scalp. When the lesions are dry, scaly patches, or ringed lesions, the scales should be removed by scraping or by rasping with soap and water, and the patches painted daily with liniment of iodine, or with tincture of iodine, to which 10 per cent. acetic acid has been added. After about a week the iodine has usually destroyed the fungus. The cure may then be completed by rubbing the patches for a few days with a 2 per cent. salicylic acid and sulphur ointment. In delicate skins iodine may prove too irritating, and in such cases 3 to 6 per cent. benzoic and salicylic acid ointment may be substituted.

In suppurative ringworm painting with iodine, followed by the application, after a week, of a 4 per cent. ammoniated mercury ointment, will generally effect a cure in about ten days.

In ringworm of the crutch and axillae more active remedies are necessary. The affected parts should be scrubbed daily, or oftener, with hot water and soft soap to remove the crusts, scales, and discharges, and an ointment rubbed in containing either 5 per cent. oxidized pyrogallie acid, which, though effective, has the disadvantage of being dirty, or a 3 to 5 per cent. benzoic and salicylic acid ointment, a valuable combination which was suggested by Whitfield. When painful fissures are present about the inguinal regions they may be healed by painting with a 3 per cent. solution of silver nitrate in spirit, or with friar's balsam. By this treatment a cure is generally effected in two or three weeks, but, to prevent recurrences, it is advisable that the parts should be painted daily for about a fortnight with a 10 per cent. solution of tincture of iodine in 60 per cent. spirit. It is important also that the underclothing which has been worn previous to the cure of the disease should be destroyed or thoroughly disinfected.

The treatment of eczematoid ringworm of the extremities, especially of the feet, requires even greater energy to effect a cure. Before applying the above remedies any vesicles should be opened and scales and loose epidermis removed, and when the lesions are acutely inflamed and purulent the inflammation should first be reduced by boracic compresses, or by soaking the feet in boracic baths or in a solution of potassium permanganate. The most intractable type of all is the *interdigital variety*, with white, thickened skin between the toes. In such cases the feet should be soaked daily in salt water—wading in the sea in summer being a valuable substitute—to macerate the thickened skin and allow the remedies to penetrate. Of these the most useful are the salicylic acid and benzoic ointment, a saturated solution of salicylic acid in spirit, the continuous application between the toes of 4 per cent. salicylic plaster, or daily painting with a 3 per cent. silver nitrate solution. The socks should be of white or natural coloured

wool, and changed at least once daily, and an antiseptic powder dusted into the feet before they are put on. After the socks have been worn they should be soaked in a solution of lysol, or stored. The boots also should be disinfected by occasionally swabbing out the inside with a 1 in 20 solution of lysol, as it is possible for the fungus to remain growing on the sodden leather inside the boot, and to work its way through the sock and reinfect the foot.

#### Scalp.

The ease with which ringworm of the scalp is spread necessitates the isolation of cases as soon as they are recognized. As a preliminary to treatment the hair should be cut short with clippers, such as are used by barbers. This is preferable to shaving the scalp, as, when it is shaved, it is more difficult to distinguish the healthy from the diseased hairs. The scalp should then be covered with a closely fitting cap made of cotton or other light material, which should be continuously worn.

The treatment of ringworm of the scalp may be considered under the two headings of suppurative and non-suppurative ringworm.

(a) *Suppurative Ringworm.*—Pustular ringworm of the scalp is much more easily cured than the dry types, as the condition is self-curative, the suppuration leading to a destruction of the fungus. The treatment consists of keeping the scalp clean by the application of boracic compresses or of mild antiseptic ointments containing boric acid, salicylic acid, or ammoniated mercury. When the swelling and inflammation subside a red bald patch is left. As a rule the hair grows over it in about six months, and only in rare instances, where superficial ulceration has supervened, does permanent baldness result.

(b) *Non-suppurative Ringworm.*—The dry, scaly forms of ringworm of the scalp are the most intractable. The difficulty of curing them is a mechanical one and due to the impossibility of reaching the fungus in the depths of the follicle by medicaments applied to the surface. As an illustration of this I may cite a case of microsporon ringworm in which I had the head kept shaved and the patches painted daily with liniment of iodide until blistering occurred. When this was healed, hairs were epilated, planted on proof agar plates, and cultures obtained. This procedure was repeated three times in six months, and always with the same result. To cure these cases it is necessary that the diseased hairs should be completely shed. Unfortunately, epilation by forceps is useless, since, however carefully it may be done, certain of the stumps are bound to be broken off and part of the infected root left behind. By far the most effective and rapid method of getting rid of the diseased hairs is by the x rays, and it is the method generally adopted. Occasionally scalps are met with that react so strongly to almost any irritant application that the x rays may be unnecessary, or the scalp may be so sensitive that the fungus itself causes so much disturbance that the ringworm becomes cured spontaneously by the hairs falling out, leaving temporary bald patches, suggesting alopecia areata, but differing from the latter in that the patches are generally inflamed and present no typical "point-of-exclamation" hairs. In infants under a year old the use of the x rays is inadvisable, and a cure can generally be effected by suitable parasiticide applications, such as ointments of salicylic and benzoic acid, iodide of sulphur, etc., as the scalp and hairs in the infant are more delicate. About puberty also, in the case of microsporon infections, the employment of the x rays is unnecessary, and parasiticides will suffice to hasten the spontaneous cure which occurs at that time.

#### Parasiticide Treatment.

When the x rays are not available, or their use is undesirable, it is necessary to resort to some parasiticide application, of which there is a large choice. It may be said that the value of a parasiticide is directly dependent not so much on its caustic action, or its power of killing the fungus directly, as on the amount of inflammatory reaction, short of ulceration, it is capable of setting up. Of the numerous irritants and parasiticides which have

been employed the two which I have found to be most useful are croton oil and sodium chloride, both of which act indirectly by the acute reaction to which they give rise.

#### X-ray Treatment.

The x-ray treatment is more rapid than any other method, and has the advantage of being painless. In competent hands it can be done, as a rule, with absolute safety, not only as far as the skin is concerned, but without any deleterious effect on the health and growth of the child; and the fear which was at one time engendered in the public mind with regard to harmful effects of the treatment on the brain is without foundation. It is an operation, however, which is by no means easy, and necessitates not only a suitable x-ray system for the purpose, and a working knowledge of the mensuration and application of the x rays, but an intimate acquaintance with the disease and its management. Without this it is a highly dangerous procedure, and may lead not only to severe dermatitis, but to permanent baldness. The casual fashion in which it has so often been undertaken in the past by those either lacking in technical skill or in knowledge of the disease has led to the most disastrous results, and has too often brought a valuable treatment into disrepute.

The x rays act simply as a depilatory. They do not destroy the fungus, and a culture of ringworm may be made from hairs which have fallen out as a result of exposure to them.

I shall not attempt here to describe in detail the x-ray technique nor the apparatus most suitable for the purpose; these can best be demonstrated in the operating room. The procedure is, briefly, to expose the whole of the scalp once to what is known as a pastille dose of x rays, which is the maximum dose the skin can stand without harmful effect, and which is sufficient to cause the hair to fall out without so injuring the papillae and follicles as to prevent regrowth. To expose the whole scalp uniformly it is necessary to divide it up into five areas, which are irradiated serially by what is known as the Kienböck-Adams method. The time occupied in exposing the entire scalp varies according to the apparatus and the methods of the operator. At Charing Cross Hospital our average time is about three-quarters of an hour, and this includes not only the time taken in exposing the various areas, but also that occupied in placing the child in the different positions, and carefully fixing the head at the required distance from the anti-cathode of the tube. During the exposure it is essential that the head be kept still. As it is dangerous for the nurse or operator to attempt any form of restraint it may be necessary, when very young or restless children have to be rayed, to employ a special couch on which the child can be strapped, and the head fixed in the required position.

The x rays have no apparent effect on the scalp at the time of the exposure, nor are any marked sensory symptoms produced by them. Young children are sometimes frightened by the noise; on the other hand, they may as readily go to sleep during the exposure. A few hours after the exposure, especially since the introduction of powerful Coolidge tubes, the child may be a little out of sorts and sick, but the indisposition is transient, and there are no after-effects. About fourteen days after the exposure a slight erythema may appear, associated with itching, and in the next few days the hair begins to fall out, the defluvium generally being complete by the twenty-first day. Eight weeks later the hair begins to grow again as a fine down, and regrowth is complete in about six months. As a rule, it is advisable to irradiate the entire scalp, even when the disease appears to be confined to one or two areas, as it saves time in the end, for the infection is almost certain to spread to other parts in the interval between the exposure and the fall of the hair, necessitating a further exposure, which may be difficult to do without overlapping.

The chief risk of the treatment is the danger of over-exposure, followed by dermatitis and incomplete regrowth of the hair. With proper care and modern technique, however, this should be a rare occurrence.

At one time it was believed to be inadvisable to x-ray children under 3 years of age, before the fontanelles had closed. Further experience has shown that, provided the child can be kept still by the use of a specially designed

couch, on which the child is strapped, younger children, and even infants of twelve months, may be treated safely by the rays.

Before exposure to the  $x$  rays the hair should be cut short with clippers and the scalp washed. Should any acute inflammatory disturbance be present, such as impetigo from scratching or irritation from previous treatment with parasitocides, especially iodine, it should be dealt with previous to exposure to the rays. If this precaution be neglected and the exposure be made on an inflamed scalp, the irritation and itching present may lead to scratching, secondary inoculation of pus-coeci, and more or less severe impetigo. After the exposure a cotton cap should be fitted to the scalp and worn continuously, and every day a 1 per cent. ammoniated mercury ointment should be gently rubbed over the scalp. On the fourteenth day the scalp should be washed with a non-irritating soap, such as Castile soap, and the washing repeated daily until the hair has fallen out. When the desquvium is complete, about the twenty-first day, the child ceases to be infectious, and may return to school, a small brown skull-cap being worn until the hair grows. The after-treatment of the scalp, until the hair returns, consists in washing and massaging it daily with almond oil or weak horic ointment, to stimulate the circulation and so encourage the hair growth.

#### Depilation by Thallium Acetate.

The most recent method of depilating the scalp is by pure thallium acetate. Thirty years ago Sabourand

attempted to produce a depilation of the scalp by injecting a solution of thallium acetate, but the treatment was so unsuccessful that it was abandoned. Recently, as the result of the experiments of Buschke and others, its use has been revived. It is given by the mouth, in a dose of 8 to 8.5 mg. per kilogram of body weight, the drug being dissolved in sugar water, and given on an empty stomach. About ten days after its ingestion the hair begins to fall out, and the depilation is more or less complete by the nineteenth day. The infected stumps do not fall so readily as the healthy hairs, so that the epilation may have to be completed by extracting them with forceps, or by applying strips of adhesive plaster. During the time in which the desquvium is taking place the scalp should be painted daily with 5 per cent. tincture of iodine, and a 6 per cent. sulphur ointment rubbed in.

As the thallium acetate acts through the sympathetic nervous system, and may cause severe general disturbance in the child, associated with drowsiness, irritability, pains in the joints, and weakness in the legs—symptoms which develop about the eighth day—it is advisable that the child should be kept in bed.

This treatment is only suitable in the case of young children up to 4 or 5 years of age, as in older children the dose necessary to cause the depilation is too great for safety. The treatment is less satisfactory than the  $x$  rays, and, owing to the dangerous general symptoms associated with it, should be employed with the greatest caution.

## THE USES AND SOME ABUSES OF HYDROTHERAPY.

BY

R. G. GORDON, M.D., D.Sc., F.R.C.P.Ed.,  
PHYSICIAN TO THE ROYAL MINERAL WATER HOSPITAL, BATH.

THERE is apt to be some mystification amongst practitioners as to the method which may underlie the madness which leads spa physicians to persuade their patients to be boiled, baked, or beaten, and induces these unfortunates to submit to these afflictions. Probably everyone is agreed that when a patient comes to a spa he benefits from the fact that he enjoys a change to a different climate, to a different environment, to different food, while he leaves his business and home worries behind him. Also he comes with the idea of having treatment, and therefore will do what he is told as to diet, exercise, and rest.

#### Hydrotherapy an Adjutant in the Cure of Disease.

With all these factors I do not propose to deal. My subject is, What do the waters do? Now at once we must admit that they do not do what they once were said to do. For example, it is recorded that at one time ladies came in large crowds for the cure at the bath in order to be relieved of the distressing malady of sterility. Nowadays, alas! this is no longer the case. Indeed, it was whispered not long ago that a sweet young thing had approached a most avowed physician, and asked demurely whether the ladies' douche was a suitable cure for the opposite condition. In those days spas were famous for the cure of the scurvy, the scrofula, and the gout—diseases which no doubt are still with us, but neither so common nor so picturesque in these degenerate days, when vitamins and soapuds have displaced the baron of beef and the strong waters.

Nevertheless, even to-day, if the credulous practitioner consults the guide to any spa and observes the table of contents, he finds two headings—indications for treatment, and contraindications for the same. The first occupies several pages, the second probably two lines—those with acute fevers who might infect the inhabitants, and those in the last stages of heart disease who might die, thereby adversely affecting the vital statistics of the famous health resort. The practitioner wonders how he still retains his livelihood, since a ticket costing a few shillings will bring practically all his patients within reach of cure, and yet we sometimes hear the spa physician complaining that he

cannot pay for the upkeep of his third Rolls-Royce. Naturally the practitioner knows that all these diseases are not cured by hydrotherapy, and is apt to class spas and all connected with them as quacks and know-alls, whose professions are closely in correlation with their ignorance. Yet this is not by any means fair to spas, and leads to a neglect of what can be done by physical means of treatment.

The confusion all arises from the pernicious habit, introduced by no less a person than Galen, of thinking in terms of diseases. Any really honest physician—I cannot here speak for surgeons—knows he never cured a disease in his life by this or that special means of treatment. On the other hand, he does know that by his general management of the patient, both from the physical and mental standpoint, he so improved the latter's power of adaptation to his environment that he recovered from the various subjective symptoms and objective disabilities which for the sake of convenience the medical profession have agreed to call this or that disease. Let us therefore get rid of the first great abuse of hydrotherapy, the idea that it cures any disease. We must realize that in its proper sphere it may be a useful adjutant to promoting the recovery of certain patients in virtue of what it does. If we wish to summarize this action we may include the effects of hydrotherapy under four heads: washing the patient within or without as the case may be; waste elimination—and if anyone should desire to change the spelling of waste I for one do not complain; alteration in the capillary circulation; and, fourthly, reflex effects from stimulation of the superficial nerve endings.

#### External Hydrotherapy.

Hydrotherapy may be administered externally or internally. Let us first consider the external application. In all seriousness I wish to lay stress on the word "wash." As we shall see in a moment, it is by elimination through the skin that hydrotherapists seek to bring about a large part of their results, and unless and until the skin is really clean adequate sweating cannot take place. It is doubtful if too much stress can be laid on the importance of the skin as an organ of elimination, and a very short experience of the maladies of middle life will convince anyone of the frequency with which the function of the skin is upset in one way or another. It is not so very long ago that every patient who came to a spa expected to be told that he was gouty, and what people expect they frequently get. Hence the old-time spa physician set up

for himself a little golden idol—the idol of uric acid. The patients were told that by means of the treatment which they underwent uric acid was expelled from every orifice of the body. It may be supposed that some sceptical patient demanded proof, and some physician fell to the temptation of a deception which, alas! is still alive among the less well informed outside and even inside the profession. It was found that at the beginning of treatment litmus paper laid on the skin turned red, while later it turned blue. What more simple? Elimination of uric acid—cure of gout? Nothing of the kind; simply washing the skin clean. If the sweat was really acid it would be a *post-mortem* phenomenon; the sweat is always alkaline, but the sebaceous detritus in a skin which does not habitually sweat freely is acid, and till that is removed the litmus paper will turn red. Having washed our patient we further proceed to make him sweat, and it is here that we may lay claim to real therapeutic results.

So far as Bath is concerned, shortly after the war Dr. Vincent Coates and the present writer managed to persuade some long-suffering ex-soldiers who were out of a job to come into hospital and submit to a fixed routine of diet and exercise. Drs. Pincent and Rayment, the bio-chemical experts in the University of Oxford, then carried out some investigations on the urine and sweat of these men, who were divided into two groups—one ingesting and bathing in mineral water only, and the other group using tap-water and producing sweat by other means. Quite definite differences were found in the excretion of calcium, sodium, and potassium ions, as well as in the distribution of the acid radicals.

So, as a result of well-authenticated and controlled experiment, we may say that the mineral water has a specific effect on excretion. Whether this is due to radio-activity, to the peculiar colloid content of the water, or to saline concentration in the water, we do not know, and the determination of these questions awaits further experiment. However, from the present standpoint this is of no great importance, since the experiments do advance the argument that it is by skin action that results are obtained.

The next effect of the external administration of water is on the capillary circulation. There is little enough exact knowledge about capillary circulation, but we recognize that at present we are only on the threshold of a very important field of investigation. It is known that only a comparatively small proportion of the capillary circulation is patent at any given time, and that changes in the relative patency profoundly modify not only the blood pressure as a whole, but also the local distribution of the circulation. The effects of capillary dilatation, therefore, which may be expected to ensue are relief to a labouring heart from reducing the resistance to be overcome, alteration in congested organs owing to the redistribution of the circulation, elimination of toxins by means of the sweat glands activated by the greater flow of blood through the skin capillaries, removal of locally deposited toxins, and softening of fibrous and scar tissue.

That reflex effects occur as a result of the stimulation of the end-organs in the skin and mucous membranes by means of the pressure and thermal effects of water is perfectly obvious to any observer, but the analysis of these from the neurological standpoint is extremely difficult and complex, and quite out of place in a paper such as this. Suffice to say that the rate and rhythm of the functions under the control of the medullary centres are profoundly modified, at least temporarily, while the general metabolic exchange is definitely altered.

We must next consider shortly by what means these results may be brought about. The effect will depend on the temperature and duration of the bath and on the pressure of the water. Baths may be cold, tepid, sub-thermal, thermal, and hypothermal.

The cold bath at less than 60° F. constricts the superficial capillaries, stimulates the nerve-endings, and causes reflex increase in the respiratory quotient and pulse rate. Diuresis is subsequently evoked, with consequent elimination of toxins, and the general metabolic exchange is increased.

The action of the tepid bath from 60° to 85° F. resembles that of the cold bath, but is of less intensity.

The subthermal bath from 85° to 98° F. is of significance

in so far as it approaches the temperature of thermal indifference (93° F.). At this point general metabolism is unaffected, and as peripheral stimuli on the circulation and nervous system are reduced to a minimum these baths are definitely sedative.

Thermal baths from 98° to 104° F. dilate the superficial capillaries and lower blood pressure temporarily. The general temperature of the body and of the circulating blood is raised. The effect on the neuro-muscular system is sedative, spasm is relaxed, and pain relieved. Elimination of toxins is greatly promoted by diaphoresis, both immediately and subsequently. The increase of body heat augments general metabolism.

Hyperthermal baths from 104° to 112° F. cause immediate constriction of the peripheral circulation, followed by dilatation. There is tonic effect on the neuro-muscular system if the duration is very short, but a marked sedative and even debilitating effect may ensue if immersion is prolonged. Elimination of toxins is promoted by diaphoresis, general metabolism is increased, and the body temperature is raised. Care must be taken in the administration of thermal and hyperthermal baths, since if too prolonged they may give rise to the condition known as thermal debility—an increasing weakness which may be of serious significance in patients with heart disease.

The pressure effects of baths are as follows:

1. General—in immersion baths. The effect of the general superficial pressure of a large volume of water on the body is to increase the rate of peripheral circulation in two ways: first, by mechanically emptying the superficial veins; and secondly, by reflexly increasing the rate of capillary flow.

2. Local—by douches. Douches may be stimulating or sedative according to their temperature and pressure. Affusion by a large volume of warm water at low pressure has a sedative effect, relaxing spasm and relieving pain and dilating superficial capillaries. High-pressure douches, especially if applied to a small area through a narrow jet, constrict the local capillaries and exert a powerful reflex stimulating effect on the neuro-muscular system and on the respiratory and vasomotor centres. It is unnecessary to point out that while such treatments are being given other methods, such as massage and electrotherapy, may be administered.

#### Internal Hydrotherapy.

Taken internally the water acts in the same way by washing and waste elimination.

Leaving aside those waters which claim a definite medicinal quality from their chemical content, such as sulphur, iron, or iodine, whose action belongs to pharmacology in its more restricted sense, the action on the stomach is mainly physical, flushing the organ with a warm non-irritating fluid, hastening the passage of its contents through the pylorus, diminishing secondary fermentation of carbohydrates, and cleansing the wall of the viscus, preparatory to the next meal. It probably causes temporary increase in the flow of hydrochloric acid and ferments, and has no aperient effect in the amounts usually prescribed.

In addition to their physical action in irrigating the tissues and promoting the removal of toxic material, these waters would seem to have peculiar properties in preventing the deposition of urates in the system. The ingestion of the water is rapidly followed by free diuresis, to which is largely due its value in gout and other conditions characterized by faulty elimination.

Administered by the rectum in the form of the Plombières douche the water acts as a cleansing agent, removing the faecal material by means of the first injection, and dissolving the mucus which may cling to the lining of the bowel by the second. This second injection may be made a useful vehicle for the administration of disinfectants, etc., in cases of bowel disease.

I think it is only right to say that in the wrongful administration of the Plombières douche lies one of the chief abuses of hydrotherapy. Only too frequently one meets patients who say, "I was at a spa two months ago and got such benefit from the Plombières treatment; but now I am as bad as ever, and I think I had better go back." This may be very gratifying to the spa, but not to the patient, and generally means that too much fluid has been injected at too great a pressure, thereby distending an already atonic colon. All that is ever needed for an efficient douche is 1½ to 2 pints from a height of

1½ to 2 feet. As a nasal, pharyngeal, or vaginal douche a bland mineral water may act as a valuable solvent of mucus, a cleansing agent, or as a vehicle for other medicaments.

So much for the use of hydrotherapeutic methods. The indications must be not for this or that disease. Let us get away from Galen and his classification of diseases and back to Hippocrates and the estimate of the total personality, bodily and mental, of our patients. When the doctor has arrived at a diagnosis, not that the patient is suffering from this or that disease, but that he requires a change of scene and occupation, elimination of poisons, or a redistribution of circulation, let him remember the possibilities of a spa and hydrotherapy. On the other hand, let him not expect results from hydrotherapy where these effects are not likely to help, for in this lies abuse of hydrotherapy. Obviously acute disease of any sort is not suited to such treatment, at least until the active stage of the disease has abated, and, above all, the submission of a case of acute rheumatism to hydrotherapy within three and probably six months of the attack is to be avoided. Where there is any cardiac affection which has not completely subsided I am prepared to say that these cases always do badly, and even cases which do not show any evidence of cardiac disease on their arrival at a spa may do so in the course of their treatment if sufficient time has not been allowed to elapse since the acute attack.

Finally, let us face the facts of hydrotherapy and realize what we can do with its aid, and confine ourselves within these limits. The worst abuse of hydrotherapy is the tendency to make a mystery of it, and to regard it in any way as a miraculous cure for any and every disease.

## OVARIAN SARCOMA IN A CHILD ASSOCIATED WITH SEXUAL PRECOCITY.

BY

A. H. SOUTHAM, M.D., M.Ch.Oxon., F.R.C.S.,

ASSISTANT SURGEON, ROYAL MANCHESTER CHILDREN'S HOSPITAL; HONORARY ASSISTANT SURGEON, SALFORD ROYAL HOSPITAL; LECTURER IN OPERATIVE SURGERY, MANCHESTER UNIVERSITY

CERTAIN tumours of childhood are associated with striking general abnormalities. This is specially true of tumours of the gonads, adrenals, and pineal body, which may be associated with precocious sexual maturity. The number of recorded cases where the abnormality has been found in association with a tumour of the ovary is comparatively small. In these cases menstruation is established at such an early age as to be truly precocious, and there is also found enlargement of the mammae and the growth of pubic hair.

The explanation of the relation of the tumour to the general condition produced has led to considerable speculation. It is well established that the gonads have a direct influence on sexual development, and it is possible that the tumour may lead to an increased formation of the tissue which influences development—the changes produced are simply the expression of a true precocious puberty. Klemperer, who accepts the view that the interstitial cells of the gonads are essential for the normal development of the sexual characteristics, believes that those tumours associated with sexual precocity are sarcomas derived from the interstitial cells. If this opinion can be accepted, then hyperactivity of the tumour tissue might be adduced as the cause of the developmental anomalies noted.

The origin of ovarian tumours is somewhat obscure. They are generally met with during the period of sexual maturity, but are also occasionally seen in children. The incidence of malignant tumours of the ovary in children increases markedly during the second decade—that is, at and after puberty. Cases occurring in children under 10 years of age are remarkably rare.

The case recorded in this paper occurred in a child in her third year of life, and a malignant tumour of the right ovary was associated with sexual precocity. The tumour was subsequently removed and the patient remains well, with no apparent sign of recurrence two and a half years after operation.

The following is the history of the case.

The patient was stated to have been a perfectly healthy child since birth, presenting no abnormal symptoms whatever. When 2 years and 10 months old she had some vaginal haemorrhage lasting three days, and shortly after this a swelling was noticed in the abdomen.

When brought to hospital there was a well-marked abdominal tumour about the size of a cricket ball, firm, rounded, and freely mobile, rather to the right of the mid-line and below the umbilicus. The child was normal in weight and height, but it was noticed that there was distinct enlargement of both breasts, conforming to the adult female type, and in addition there was a marked development of the pubic hair.

Whilst under observation in the Children's Hospital she had a second vaginal haemorrhage, which occurred twenty-eight days after the previous period. In view of these symptoms a provisional diagnosis of an ovarian tumour was made; a radiogram proved negative, and cystoscopic examination showed that both kidneys were acting normally.

On August 26th, 1925, the abdomen was opened by a right paramedian rectus incision and a freely mobile tumour was found arising from the right ovary. It was free from adhesions, and there were no peritoneal or glandular metastases. The uterus appeared large for the child's age; the left tube and ovary were normal. The tumour and right Fallopian tube were removed intact and the wound closed. The child made a straightforward recovery from the operation.

The specimen was examined by Dr. A. E. Somerford.

### Pathological Report.

The tumour, which weighed 225 grams, was about the size of a cricket ball, and was rounded in form. There was no distinct capsule. It was practically a solid tumour, but on section there were some cystic areas of small size filled with altered blood. Microscopically the growth had the structure of a small rounded sarcoma in which there were numerous areas of haemorrhage. There were no remnants of ovarian tissue present.

### Subsequent History.

Since the operation the child has developed normally. The breasts have decreased in size, there has been no further menstruation, and the pubic hair has been lost. A recent examination two and a half years after operation has revealed no evidence of recurrence of the tumour, and no metastases could be discovered.

### Remarks.

The points of special interest in the case are the rarity of the condition and the early age at which the tumour was discovered, most other cases recorded occurring in older children.

The nature of the tumour was established pathologically as being a sarcoma, and it is interesting to note that the ovary itself could not be recognized either by the naked eye or by the microscope, being completely incorporated in the tumour.

After removal of the growth the condition of the child has returned to normal, and although the tumour was histologically malignant the subsequent history of the case has been satisfactory.

## THE CAUSE AND TREATMENT OF THE CRISIS IN LOBAR PNEUMONIA.\*

BY

ALEXANDER CANNON, M.B., Ch.B. LEEDS,

GOVERNMENT MEDICAL OFFICER, HONG-KONG.

In South China and Hong-Kong quite 90 per cent. of the cases of lobar pneumonia are caused by the pneumococcus of Fraenkel. The crisis is not due to immunization, for if this were the cause the fall in temperature would be gradual as the immunity increased, and hence the curve would drop very slowly over a number of days. The drop in temperature is, however, sudden, often occurring within a few hours, and hence the cause cannot be explained in this way.

The pneumococcus grows very readily on blood agar, producing a characteristic green coloration; no other known organism can produce this particular green coloration on blood agar. Moreover, it is known that after a time the pneumococcus ceases to grow in the same medium, and it has been shown experimentally that this is due to the formation of hydrogen peroxide or some other peroxide, and that no other agent can produce the same identical colour.

Numerous experiments show that the pneumococcus

\* Modified by the author from a lecture delivered to the Hong-Kong Branch of the British Medical Association.

produces the gas oxygen, which acts favourably on its growth for a time; but when sufficient oxygen has been set free to benefit and make the "soil" more suitable for rapid growth the organism sets free oxygen in excess, which has been shown to be very detrimental to growth, so much so that the cocci die. There is a limit to the utility of oxygen, for beyond a certain strength it defeats the object for which the organism apparently produced it. When this point is reached in pneumonia the crisis is reached, and the temperature rapidly drops to normal or subnormal; in this way Nature provides its own cure. In experimental investigations the usual laboratory methods were used for the collection of the gas produced by these organisms, and without exception the gas was proved to be oxygen.

#### *Method of Administering Oxygen in Pneumonia.*

There is a very small point which is of great importance in the use of oxygen in pneumonia, and is the secret of the success which has followed my treatment of all pneumonia cases: the oxygen should be used warmed. In the past the use of oxygen has been the cause of more deaths in pneumonia than one cares to contemplate, simply because it was administered cold and not warmed to the required temperature; hence the lungs were chilled and the patient could not stand the shock. The oxygen should be heated by passing the gas through coiled Littré's tubes immersed in a water-bath kept at a temperature of about 120° F., the gas being passed through the tube at a slow rate, which is gauged by the comfort of the patient, who breathes quietly and does not complain of the "choking" feeling which occurs when the gas is administered too quickly. By keeping a thermometer in the tube it was found that the gas passing through at this very slow rate was about 99° F. when the water-bath registered 120° F. One thing to watch is the risk of sudden collapse when the crisis occurs; this can fortunately be avoided by the daily administration of pituitrin, 1/2 c.cm. being administered hypodermically morning and night, the heart action being safeguarded by the old-time proven remedy of digitalis administered from the onset of the disease; the omission of this has been responsible for the loss of many a case of pneumonia. Every clinician can verify the fact for himself that oxygen rapidly cures these cases, and every bacteriologist can satisfy himself that the pneumococcus alone among micro-organisms can produce the particular green coloration to which reference has been made.

That the foregoing method of administering oxygen is effective in the treatment of pneumonia is evident from the clinical observations recorded below. Among the Chinese the disease is more common in males than in females. As medical officer in charge of H.M. prisons in Hong-Kong and Li Chi Kok I have still to report my first female pneumonia patient, although it is quite a common disease among the male prisoners. My statistics show noticeable epidemics, when house after house was infected in Canton, and then would come a spell when for months not a single case of pneumonia would occur. The epidemics were most prevalent in May, June, and September. Persons such as police and coolies, who are exposed to weather changes, showed a marked preponderance of cases. Most patients had a previous history of similar attacks having occurred one, two, or three years before, which is a point of great interest. Most attacks occurred after the moist heat (humidity of over 95) so characteristic of South China; the majority of the patients were whisky drinkers.

#### *Clinical Observations.*

A rigor was the initial symptom in 65 per cent. of the cases, and 25 per cent. had a noticeable malar flush, often simulating typhoid fever; this latter disease was eliminated by laboratory methods and clinical findings.

Headache was a prominent feature in 29 per cent. of cases. Pain in the right side was complained of by 27 per cent., and pain on the left side by one patient.

In 84 per cent. of the cases the respirations at the first visit ranged between 40 and 47; in 16 per cent. of cases 27 to 34. Within six hours of commencing treatment in over 50 per cent. of cases the respirations had come down to somewhere in the region of 27. Within two days of treatment the respirations ranged between 16 and 20, and the patient was apparently well on the third day.

With three exceptions the temperature recorded when the patient was first seen was between 103° and 104° F. In one of

the three exceptions the temperature did not rise above 99° F., although the physical signs and symptoms were definitely those of lobar pneumonia; this patient had also a marked pleural effusion on the left side. In all cases in which oxygen was administered the same day for a quarter of an hour, every hour, passing the gas through a Littré's tube, the patient's temperature reached the normal within three days.

The following case, selected at random from over one hundred cases, is typical of all patients so treated:

A man, aged 48, when first seen had a temperature of 103.8° F.; the respirations were 40, the pulse 109, and the malar flush was marked. There was frontal headache, and pain on the right side of the chest which was said to be much increased by deep breathing. He wanted to cough, but was prevented by the pain. The urine was very dark, with a trace of albumin; the faeces were well formed, but had an offensive odour. He complained of slight thirst, but when water was given he refused it.

Oxygen was administered as previously described. Six hours later the temperature was 102° F., the respirations were 25, the pulse 85, and the headache had almost gone. The pain in the chest was much relieved; he was able to cough, but there was no sputum. The urine was not so dark, but contained albumin. The patient had not had any further rigors, though there had been some previously. Although breathing was still not as free and easy as normal, nevertheless the patient had a good sleep.

The next day at 10 a.m. the temperature was 102° F., the respirations 24, and the pulse 68. There was no pain in the chest, and no headache. The sputum was free and thick, but only suggestive of the "rusty" colour. The urine contained no albumin. He had passed faeces which were well formed and normal in colour. The typical physical signs of lobar pneumonia were disappearing, and fine crepitations were heard at the base.

On the third day at 4 p.m. the temperature was 98° F., the respirations 15, and the pulse 70. The sputum was diminishing, the urine was dark, but contained no albumin, and the patient had passed a normal motion.

Recovery was rapid and complete, the disease being apparently cured within three days, the patient getting up on the fourth day, and out on the sixth day. When last seen he was enjoying a swim.

The crisis appeared in most cases to occur during the night, when the patient was asleep. None of these patients felt weak or complained of any disability whatsoever, and they breathed rather freely all the time.

Oxygen does more than merely increase metabolism: it destroys disease.

## **DANGER OF INTRAVENOUS CALCIUM THERAPY.**

BY

W. D. M. LLOYD, M.D., M.Sc., L.M.C.C.

(Department of Pharmacology, University of Western Ontario Medical School, London, Canada.)

### **INTRODUCTION.**

CALCIUM has been given intravenously in the treatment of lead poisoning, infantile tetany, tuberculosis, Bright's disease, haemorrhage, heart disease, and in the pre-operative preparation of jaundiced patients. Cushny (1924) stated that calcium injected directly into the blood stream acted much like digitalis in that it accelerated and strengthened the heart beat in small doses, but in large doses it seemed to be poisonous, tending to bring the heart to a standstill. Brown, MacLachlan, and Simpson (1920) observed that doses of 1.25 grams of calcium lactate, given intravenously to infants suffering from tetany, resulted in drowsiness, dyspnoea, cyanosis, and sometimes collapse. Neumann (1920) reported favourable results in cases of haemorrhage and of acute and chronic diarrhoea from the intravenous injection of 5 to 10 c.cm. of a 10 per cent. solution of calcium chloride. Grove and Vines (1921) pointed out the value of the intramuscular injection of 100 minims of a 1 per cent. solution of calcium chloride in cases of haemorrhage. Walters (1921) reported the use of calcium chloride in 10 per cent. solution intravenously in the pre-operative preparation of jaundiced patients. The treatment was efficacious in producing a shortening of the blood-clotting time. This author stated that calcium in small doses, as 10 c.cm. of a 10 per cent. solution, might be given intravenously without harm.

In a further study of the action of calcium chloride given intravenously Walters and Bowler (1924) found that approximately twice the amount of the salt was required to raise the blood calcium of jaundiced dogs to the same level as that of normal dogs, and this in spite of the fact that the blood calcium content was practically the same in the jaundiced and normal dogs before and after

injection of a lethal dose, which suggested a calcium deficiency in the jaundiced animals that was not apparent. They noted that when the drug was administered intravenously to patients there resulted a quickening of the pulse rate and a sensation of heat over the entire body. They observed that this was the effect to which Herschelsolm and Maendll gave the name of "dynamic effect" of intravenous administration. The same phenomenon was seen by these latter authors to follow the injection of quinine, dextrose, hexamethylenetetramine, and urea; it proved transitory. At the same time, Walters and Bowler made comprehensive studies of the effects of intravenous injections of calcium chloride on the electro-cardiograms of dogs. A 10 per cent. aqueous solution of the salt was used and injected at the rate of 1 c.cm. per minute. The injection of toxic doses into the blood streams of dogs brought about various alterations in rate, disturbances of conduction, ectopic origins of impulse, and, when carried to a still further point of toxicity, disturbances of the fundamental co-ordination of the heart, and ventricular fibrillation, which was followed by death. Moderate doses caused only an alteration of the pulse rate; this occurred consistently at an early point in the injection, but was produced by smaller amounts of the solution in the normal than in the jaundiced dogs. After the maximal acceleration was reached there was a marked variation in rate, following which the initial maximum was rarely exceeded. Conduction disturbances appeared, marked by short recurring periods of heart block, and notched Q.R.S. complexes, which made their appearance more frequently as the continued injection assumed a more toxic effect. There next occurred an increase in the amplitude of the T wave with a gradual encroachment on the Q.R.S. complex, ventricular fibrillation, and death. The ectopic origin of impulses was demonstrated by the appearance of inverted T waves and periods of nodal rhythm. The rate at which the injection was given was of some importance because the concentration of calcium in the blood stream seemed to be a factor in the toxicity of any dose. In two instances following a rapid injection the calcium content of the blood taken from the heart immediately after death was twice that of the blood taken from the external jugular vein. The investigators ascribed the death following large doses of calcium to the occurrence of ventricular fibrillation rather than to a calcium rigor.

Singer (1921) reported the use of calcium intravenously (1 c.cm. of a 10 per cent. solution) associated with the administration of digitalis by the mouth in the treatment of cardiac diseases with oedema. The calcium increased the tone of the ventricles, effecting a slight rise of blood pressure, slowing the pulse, and causing an occasional diuresis. Calcium he believed to be "the whip and the rein" for digitalis.

Popescu-Inotesti (1925) was able to induce phenomena of sympathetic excitation—namely, tachycardia, hypertension, mydriasis, hyperglycaemia, and sometimes tachypnoea—by the intravenous injection of small doses of calcium (0.1 to 1 gram); the use of larger doses (1.5 to 4 grams) caused excitation of the parasympathetic with bradycardia, miosis, and bradypnoea. The hypertension in the first instance he believed to be due to direct stimulation of the muscular fibres of the vascular wall.

Seelig (1925), calling attention to the possible ill effects upon the heart and subcutaneous tissues of the intravenous injection of the 10 per cent. solution of calcium chloride, recommended in its stead a dose of 50 c.cm. of a 1 per cent. solution, which would not cause subcutaneous sloughing, and which, particularly when injected slowly, had little if any deleterious effect upon the heart.

During the course of some experiments in our laboratory electro-cardiographic records were taken of the heart of man during and following calcium administration intravenously. The technique and results of these experiments are described below.

#### EXPERIMENTAL TECHNIQUE.

The solutions used for intravenous administration were 1 per cent. and 10 per cent. solutions of calcium chloride. These solutions were accurately prepared with chemically pure anhydrous calcium chloride and distilled water; they were sterilized by autoclaving. The skin of the subject's right arm in the region of the antecubital space was sterilized in each case with alcohol, and the injections were made into the median cubital vein. Needles and syringes were sterilized by boiling on each occasion, a 50 c.cm. syringe

being employed in the first experiment, when 50 c.cm. of a 1 per cent. solution of calcium chloride was injected, and a 10 c.cm. syringe in the second experiment, when 4 c.cm. of a 10 per cent. solution of calcium chloride was administered. The injections were given slowly. The author, a 135 lb. man, acted as the subject of the experiment in each instance.

During both experiments electro-cardiographic tracings were taken of the normal period, the period of injection, and, in the first experiment, the period after the in-

Electro-cardiogram (Lead 2) of the author's case, showing sino-auricular block occurring during intravenous calcium administration.

jection, the leads of the electro-cardiograph being in each case the right arm and left leg.

#### OBSERVATIONS.

In the first experiment, when 50 c.cm. of a 1 per cent. solution of calcium chloride was injected intravenously, an electro-cardiogram before, during, and for eight minutes after injection was taken. No subjective or objective symptoms beyond the normal were observed in the subject of experiment. The electro-cardiogram showed no changes from the normal during and following the injection other than a slight increase in the heart rate during the period in which the needle penetrated the skin.

The second experiment, in which 4 c.cm. of a 10 per cent. calcium chloride solution were injected intravenously, was more productive of results. When 2 c.cm. of the solution had been injected the subject experienced a sensation of warmth over the entire body, accompanied by slight headache and a feeling of fullness in the head. It was decided to continue the injection. Dizziness occurred during the period of injection of the second 2 c.cm., and this was closely followed in the course of the next three seconds by syncope, respiratory failure, upward deviation of the eyes, dilatation of the pupils, rigor of the masseters, and asphyxial extensor spasm and rigidity. The string of the electro-cardiograph at this time was seen to be standing still. The subject was taken away from the electrodes, placed in a supine position upon the floor, and artificial respiration instituted. An attempt was made to massage the heart through the abdominal wall and diaphragm at the

left costal margin. In the course of four or five minutes voluntary respiration was again established, the pupils contracted, and consciousness was regained. No residual effects were noted.

The examination of the electro-cardiogram during this period showed the normal cardiogram to be replaced by one in which the rate of the heart was reduced to one-half. No changes were to be seen in the P.Q.R. complex at the time of this change in the frequency. Each wave possessed its normal order, time relationship, and character. After this bradycardia had lasted for ten seconds it was replaced by a series of small waves, which were suggestive of vibration of the string. There is no evidence in the cardiogram that the ventricle was beating during this period. At the end of the curve, when the subject was removed from the electrodes, these small fibrillary waves were less frequent but of greater amplitude. There was as yet no evidence of the R wave of ventricular contraction. The tracing was that of a prolonged sino-auricular block.

#### COMMENT.

From these few observations it is not possible to reach any conclusions as to the effect of calcium upon the normal electro-cardiogram.

Whether the effects noted in the second experiment are evidences of vagal stimulation or a direct action upon the genetic nervous system of the heart independently of any extrinsic nervous supply it is impossible to state. The nature of the results obtained rendered it inadvisable to repeat the experiment following atropinization.

The disturbances of conduction noted are somewhat in accordance with those obtained by Walters and Bowler in the dog. I simply desire to call attention to the occurrence of cardiac disturbances of conduction as a result of intravenous calcium administration in a dosage that has been commonly used.

#### SUMMARY.

The intravenous use of 4 c.cm. of a 10 per cent. solution of calcium chloride is dangerous. The electro-cardiogram shows what we believe to be a sino-auricular heart-block.

To my chief, Professor J. W. Crane, and to Drs. Wand, Gordon, Kitchen, and Vine, I wish to acknowledge my gratitude for their help in the performance of this study.

## A MIXED TUMOUR OF THE NASOPHARYNX.

BY

JOHN E. G. MCGIBBON, M.B., B.S.LOND., D.L.O.,  
HONORARY ASSISTANT AURAL SURGEON, EYE AND EAR INFIRMARY,  
LIVERPOOL.

*With a Pathological Report by*

J. M. BEATTIE, M.A., M.D.,

PROFESSOR OF BACTERIOLOGY, UNIVERSITY OF LIVERPOOL.

It is recorded by Sir StClair Thomson that "neither simple nor malignant neoplasms are found, except rarely, in the post-nasal space. The innocent growths are so uncommon that every new formation in this region should be looked on with suspicion." On the other hand, Sir William Milligan, opening a discussion on nasopharyngeal growths at the Laryngological and Otological Sections of the Royal Society of Medicine, stated that growths in the post-nasal space are not uncommon, but that their presence is frequently overlooked; and further, that the principal

varieties of new growths in this region are nasopharyngeal fibromata, angiomas, endotheliomas, carcinomas, and chondrosarcomata.

The report of the following case is therefore considered of interest because of the lack of references to similar cases in the English textbooks.

A boy, aged 7 years, was sent to St. Helens Hospital for the removal of adenoids; he suffered from frequent colds and nasal obstruction. On examination by anterior rhinoscopy nothing abnormal was found; posterior rhinoscopy was difficult, but the lower pole of a smooth greyish-pink tumour was seen partially filling the left nasopharynx; this mass did not bulge the soft palate of that side. By digital examination a firm sessile tumour, about the size of a small nut, was palpable, occupying the left side of the post-nasal space. The tumour did not bleed during examination, and appeared to spring from the lateral wall of the nasopharynx, between the left choana and the Eustachian orifice. There was no history of epistaxis or pain, and no evidence of involvement of the middle ear or of the neighbouring lymph glands.

A diagnosis of nasopharyngeal fibroma was made, and subsequently the tumour was removed with post-nasal forceps without undue haemorrhage. The child was examined three months later, when the nasopharynx appeared clear.

Professor Beattie kindly examined the specimen and made the following report:

This tissue consists of an area of irregular cartilage, an area of adenomatous tissue, the acini being lined by a high columnar epithelium (similar to the lining in the gland spaces of the ovary), and a cellular area mainly with round mononuclear cells. The section suggests a tumour of congenital origin from some abnormal structure.

Brown Kelly has classified a group of tumours occurring in the pharynx as follows: (1) teratomata, (2) teratoids, and (3) mixed tumours—"arising from cells at the junction of two types of epithelium. Some may assume mildly malignant characters." The tumour reported above belongs to the last class, and is more correctly called a blasto-teratoma; it is similar to tumours arising in the parotid, submaxillary region, lip, palate, orbit, and, as recently described, in the molar glands.

## A METHOD OF TREATING FRACTURES OF THE CLAVICLE WITH DISPLACEMENT:

BY

G. W. MILROY, M.B., CH.B.,  
WIGAN.

PROBABLY the most commonly used method of treating simple fractures of the clavicle with displacement is either that originally described by Sayre, or the bandage devised by Doughton. One great disadvantage of the former method of fixation is the fact that the strapping used to support the elbow so often slips over the point of the olecranon process, allowing the arm to drop, with recurrence of the original displacement.

In an endeavour to avoid this difficulty the plaster is sometimes applied with the adhesive side next to the skin. This certainly prevents any slipping, but it does not allow of accurate adjustment, and also gives rise to much discomfort, often amounting to actual pain, particularly around the point of the elbow. This pain seems to be equally severe whether a slit for the olecranon process is made in the plaster or not. If, on the other hand, Douglas's method of bandaging is employed, the original disadvantage is again evident. The bandage as a whole tends to become loose, and the final turns round the elbow and over the opposite shoulder slip off the elbow and allow the arm to drop. The bandage may remain in good position during the day, but when the patient is in bed, and particularly if he is somewhat restless, as these patients usually are, the bandage will soon work loose. It is a common experience to find a patient with a fractured clavicle, which has been reduced and firmly bandaged on one day, returning next morning with the bandage loose and the deformity renewed.

To overcome these difficulties I have been using a modification of Sayre's method which has given great satisfaction. The method devised is as follows.

Two five-foot lengths of calico bandage are required. The first, as in Sayre's original method, is looped loosely round the affected arm as high up as possible, the loop being fastened with a safety-pin. The usual pad is placed in the axilla, the shoulder is pulled back as far as possible, and the bandage is carried across the back of the trunk, round across the chest, and pinned to itself just beyond the loop round the arm.

The second bandage, which should be at least six inches wide, is slit from one end for a little less than half its length, and is then applied to the injured arm in the form of a sling, with the two tails to the front, in the following manner. The uncut end of the bandage runs from the unaffected shoulder across the back to the elbow of the affected arm, which it supports, a pad of wool being placed between it and

the olecranon. The bandage is adjusted in such a way that the two tails originate an inch or so in front of the point of the elbow. These tails are then carried round opposite sides of the forearm, and are twisted together once or twice as near to the bend of the elbow as is possible. They are then carried forward as spirals in opposite directions round the forearm, thus crossing on the dorsal aspect of the middle of the forearm, and also at the front of the wrist, where they are again twisted together and carried on as one to the shoulder. The elbow is then drawn upwards, forwards, and inwards to the required position, and secured by tying the ends of the "sling" over the unaffected shoulder. The sling effect of the second bandage has been found to be very stable; the first loop of the tails round the forearm just beyond the elbow effectively prevents any slipping off the elbow.

The spiral round the forearm will be found to support the forearm comfortably in the usual position across the chest, and the combination of the two bandages and the axillary pad will supply the force necessary to carry the lateral fragment of the clavicle upwards, backwards, and laterally, which is so essential for a perfect result in these cases.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### VARICOSE VEINS IN THE BROAD LIGAMENTS.

I HAVE been repeatedly struck by the frequency with which enormous varicose veins of the pampiniform plexus occur, but I have been unable to find much written about them, and very little concerning their treatment. The questions naturally arise whether these varices are themselves the cause of abdominal and pelvic symptoms, and how they should be treated.

Most of the patients I have seen have complained of persistent pains of a dull aching character, and a weight in the pelvis; most of them also had vaginal discharge, which in some cases was gonococcal and in others gave pure cultures of *B. coli*. A few patients had been cured, with no benefit. On examination they complain of sharp pain on pressure in the fornices, similar to that of inflammatory adnexal disease; eventually the pain and discharge have demanded an exploratory operation.

Many of the patients have been under 35 years of age. The menstrual history is normal. An operation discloses no tubal disease, no adhesions, and no uterine displacements; the uterus is in some cases slightly enlarged, but there is present a huge black mass of varicose veins. In

all cases one condition has been very constant—namely, cystic enlargement of both ovaries. It seems unlikely that this cystic state of the ovaries is the cause of the pains, because the condition is often seen when operation is performed for other abnormalities.

We are faced with the following problems: a patient, aged, say, 35, comes with constant uterine discharge and pain, enlarged cystic ovaries, and this condition of varicose veins in the broad ligaments. What is the correct treatment? It seems unlikely that the discharge will cease unless the uterus is removed, which is scarcely justifiable at that age.

Again, should the cystic ovaries be removed? How should the varices be treated? What is to be done with a patient who has no uterine discharge, and whose only abnormalities are varices and cystic ovaries? I put these questions with the hope that experienced gynaecologists and surgeons will give us the benefit of their advice and practice; at present the subject appears to me very full of difficulties.

C. L. GRANTVILLE-CHAPMAN, F.R.C.S.I.,  
Surgeon, Grimsby and District Hospital.

#### FOREIGN BODY IN THE BLADDER CAUSING CALCULUS FORMATION.

FOLLOWING the case reported by Mr. Guy Chambers in the *Journal* of November 5th, 1927 (p. 827), in which a hairpin formed the nucleus of a vesical calculus, and Mr. A. Ralph Thompson's report of five cases of foreign bodies in the urinary bladder (January 14th, p. 51), details of another case should also prove of interest.

The patient, a woman aged 67, is suffering from secondary dementia following manic-depressive insanity, and shows marked amnesia. For some time she suffered from incontinence of urine, which appeared to be more of an inconvenience to others than to herself. At no time did she complain of any pain, nor, in fact, was any clinical history procurable from her. On vaginal examination she was found to have a large hard tumour bulging into the anterior wall of the vagina just behind the external orifice of the urethra; this suggested a stone, and the diagnosis was confirmed by the passage of a bladder sound. In view of the probable presence of a foreign body, I decided to remove the stone by the suprapubic route. When the bladder was opened the stone was found to be impacted over the internal urethral orifice, and to be fixed in this position by a hairpin, the free extremities of which were embedded in the bladder wall. The removal was difficult, the more so because the bladder wall was so friable that it would scarcely hold a stitch. The stone was about the size of a large egg; it weighed 123 grams, and was composed mainly of urates and phosphates.

As shown in the illustration, the offending hairpin traverses the stone in the longitudinal axis, and has evidently formed the nucleus around which the stone was

formed. The length of time taken by the stone to form may be guessed at from the patient's history. It may be assumed that the introduction of the hairpin occurred during a phase of mania, and that it therefore had been in the bladder for upwards of two years. It is extraordinary that the patient did not complain of pain and that the hairpin did not perforate the bladder, in view of the fact that both extremities were embedded in the wall.

There was some degree of cystitis present before the operation, but despite this the patient's condition three weeks after the operation is favourable, and she continues to improve.

I am obliged to the subcommittee of the hospital for permission to publish this case.

Colney Hatch Mental Hospital, N.11. M.B., Ch.B.Glas., F.R.C.S.Eng.

**DYSTOCIA ASSOCIATED WITH A VAGINAL BAND.**

THE following case appears to be worthy of record inasmuch as an occipito-posterior presentation in a primipara was complicated by a vaginal band.

In a primipara, aged 23, who had never previously had a vaginal examination, labour began in the morning; progress was slow, the pains being slight, and she was first examined in the afternoon. When making the first vaginal examination there appeared to be some fold of mucous membrane in the neighbourhood of the os, which admitted two fingers, the whole of the parts being soft. Seen again at 6 p.m. very little progress appeared to have been made, but the presentation was diagnosed as being occipito-posterior. At 8.30 the os had reached the size of a five-shilling piece, and the existence of a peculiar strand of mucous membrane had become more evident. Labour was progressing slowly, but the pains were not very strong, and the membranes had not broken. The patient was examined again at 10.30, when it was found that a finger could be hooked round what appeared to be a fleshy band lying up against the expanding os. The patient was put into the lithotomy position and anaesthetized, and a vaginal speculum was inserted. It was then found that a fleshy band extended from the caruncula to the posterior vaginal wall far back; it was about half an inch in thickness in its thinnest part. It was ligatured in two places and divided. Labour then progressed in the usual way, delivery being accomplished by turning the head and applying forceps.

The case derives special interest from the presence of the thick vaginal band; which would appear to be of the nature of a partly bifid vagina. I can find no reference to this condition in the textbooks.

Docking, Norfolk.

W. W. JEUDWINE, M.D.

**DELAYED INTRACRANIAL HAEMORRHAGE.**

THE following clinical details of a case of cerebral haemorrhage occurring several days after an accident seem to be worthy of record.

A girl, aged 2, while playing, fell and struck her head against the corner of a sideboard. She was stunned for a few moments, but quickly recovered, and her foster-mother, a careful woman, did not think medical advice necessary. There was a small bruise and abrasion on the forehead, but nothing else was detected. The child remained in apparently normal health until eighteen days later, when she stopped eating while having a hearty breakfast, clenched her teeth, and died within a minute. No other history of further symptoms, such as vomiting, headache, or drowsiness, could be elicited after careful questioning of those who had been in contact with the child.

A post-mortem examination revealed a bruise about one inch in diameter on the left temple; there was no fracture of the skull. Under the dura was found a considerable quantity of blood clot, probably about three ounces. The left frontal lobe of the brain showed a contusion corresponding with the position of the external bruise, and there was a similar contusion caused by "contrecoup" on the right occipital lobe. The subdural haemorrhage appeared to have come from the ruptured meningeal vessels over the frontal lobe contusion. There was no haemorrhage into the ventricles. The other organs of the body were normal, and no food was lodged in the air passages or gullet.

The points of interest in this case are: (1) the comparatively slight nature of the original injury and of the immediate symptoms; (2) the long latent period of apparently perfect health; (3) the sudden and unexpected death.

Worcester.

**SCORBUTIC SWELLING SIMULATING AN ACUTE BURSITIS.**

THE following case may be of interest to readers of the *Journal*. A woman, aged 25, sought relief for a swollen knee. She had a large pre-patellar swelling, the skin over which was thinned and glazed, suggesting an abscess on the point of rupture. Free fluctuation was present. The swelling was about the size of a large orange, and the patient stated that it had been causing her considerable pain since it started, two months before her visit to me.

I anaesthetized the part by means of a 2 per cent. solution of novocain, injected into the medial aspect of the thigh just above the knee. Using a 20 c.cm. syringe, I pushed a long needle into the swelling, penetrating the skin some three inches away from the swelling itself. On withdrawing the piston some blood began to flow into the barrel, and I realized that, instead of a pre-patellar abscess or bursitis, I was dealing with a sanguineous scorbutic swelling, scurvy being very prevalent amongst the natives in these parts. I removed nearly ten ounces of dark sanguineous fluid, and the patient derived great relief.

**Reports of Societies.****TUBERCULOSIS OF THE URINARY TRACT.**

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland on March 30th, the president, Mr. ANDREW FULLERTON, in the chair, Mr. HENRY WADE read a paper on the surgical pathology of tuberculous disease of the urinary tract, and showed lantern slides.

Mr. Wade said that during a period of five years to 1926 he had had 57 cases of renal tuberculosis under his care; of these patients, 21 were males and 36 females, the average age of the males being 29 and that of the females 34 years. The average duration of their illness was two years and five months. The outstanding complaint in 49 cases was frequency of micturition. Tubercle bacilli were found in the urine in 26 cases. The importance of a preliminary x-ray examination of the entire urinary tract was emphasized, since this not infrequently revealed the presence of tuberculous disease in one kidney. Cystoscopic examinations were performed in every case; the average number of cystoscopic examinations was 1.6. In virtually every case the bladder capacity was found to be reduced, varying from 10 c.cm. to 300 c.cm., the average being 156 c.cm. The degree of the diminution of the bladder capacity was an approximate indication of the severity of the case, and the increase in the bladder capacity subsequent to operation was a very valuable indication of the improvement that had occurred. The presence of a "golf-hole" ureter was diagnostic of tuberculous disease in the kidney above. The earliest indication was a swelling of the mucous membrane with congestion and oedema. In every case bilateral ureteral catheterization was attempted and was achieved in the majority. Pyelograms were taken on both sides; the author had found no harmful results follow this practice. Where the catheter could only be passed for a few centimetres a ureterogram was taken. The pyelographic findings varied with the stage and type of the disease present. In the earlier type of case which had proceeded to cavity formation the outline of a normal pelvis and normal calyces was seen at one part with a filling defect from cavity formation communicating with the pelvis at another part; this appearance was diagnostic. The appearances seen in a ureterogram were also diagnostic where the ureter was involved; these were the irregular dilatation of the channel and its irregular outline. In an early case the amount of secretion from the diseased kidney might be greater than from the healthy side. In cases where the examination was difficult chromocystoscopy was of value, especially to indicate the situation of the orifices. In a very occasional case, where doubt still existed, certain methods of operative surgery had been recommended as an aid to diagnosis. Catheterization of the ureters through the open bladder was not advocated. Examination of the ureter through a gridiron incision in the loin was of value in certain cases. The treatment of tuberculous disease of the kidney advocated was nephrectomy where the disease was unilateral, since a spontaneous natural cure of renal tuberculosis did not occur. Of the 57 patients, 53 were operated on, 2 were found to be inoperable, and 2 declined operative treatment; 1 patient died in hospital from a cardiac thrombus. In 34 patients the wounds healed by primary union; their average stay in hospital was twenty-one days. Twelve patients left hospital with a small sinus still unhealed; 6 left with a larger sinus, the result of partial breaking down of the wound. In one case the wound entirely broke down, but completely healed five months subsequently. Every patient was re-examined on several occasions. A complete cure was obtained in 34 cases; 11 patients were improved, and 6 died after leaving hospital. Repeated cystoscopic examinations showed that, where tuberculous ulcers had been present on the surface of the bladder, these usually disappeared rapidly, first from the base and lateral walls, and later from its roof. Frequency of micturition might persist, being due to a chronic ulcer or to a localized interstitial cystitis; in three cases it was found to be due to persistent, non-

suppurative streptococcal cystitis. In the 6 patients who died after leaving hospital, death was due to dissemination of the tuberculous infection in 2 cases; 2 died from the continued activity of the unremoved infection, and 1 died three and a half years after the operation from anuria. He had completely recovered from the tuberculous infection, and the anuria was due to hydronephrosis originally produced when the bladder was in persistent systole prior to the operation. The sixth patient died from a primary adenocarcinoma of the liver four and a half years after the right kidney was removed for tuberculous disease. There were no signs or symptoms of disease of the urinary tract. Complete microscopical sections of the entire organ were made in the 53 kidneys removed.

The PRESIDENT said that ill health preceding tuberculous disease of the kidney was in a large number of cases entirely absent, and patients suffering from this disease usually only consulted a surgeon on account of frequency of micturition, which became so severe as to interfere with their work. The shadows which were found in the region of the kidney and ureter were pitfalls, and it was only by the ureteral catheter and pyelograms that it was possible to differentiate them, and to show that they had any relation to the kidney. Diminution of bladder capacity, which was a feature of cases of tuberculous of the kidney in the early stages, was also very important in the later stages. The presence of tubercles on the mucous membrane of the bladder was mentioned in textbooks, but his experience was that these were not often seen. Unilateral diuresis was one of the earliest and most important signs of tuberculous of the kidney.

Mr. A. A. McCONNELL referred to the necessity of very exhaustive preliminary examination in cases of tuberculous of the kidney, and said that in renal disease, if it was not possible to make a diagnosis before operation, it was very unlikely that one would be made subsequently. He himself did not use pyelograms, since he felt that the less manipulation of the kidney practised in tuberculous cases the better it would be for the patient. He had seen cases in which the bladder had been severely involved with tuberculous at the time of operation, and in which the ureters could only be found by the injection of indigo-carmin, though there had been no bladder symptoms whatsoever.

Mr. SEYON PRINGLE said that in his experience nearly 50 per cent. of late cases were obviously bilateral and inoperable, and he referred to the use of tuberculin in these cases. When it was difficult to make a diagnosis, convalescent treatment, after a course of tuberculin, rendered it possible to come to a more definite conclusion regarding operation.

Mr. L. G. GUNN thought that cases of bilateral tuberculous were not rare. In the last few months he had seen five cases, all of which, in his opinion, were inoperable. He considered it unwise to perform nephrectomy in cases in which there was any disease in the other kidney, or in any other part of the system, joint, bone, or lung. Tuberculin in a great many cases prolonged life, but nephrectomy was the ideal treatment for cases in which tuberculous disease was confined to one kidney, one ureter, and the bladder.

Mr. WADE, replying, said that he had never seen tuberculous nodules on the surface of the bladder, and agreed that more was learned in these cases before an operation than at one.

### SURGICAL CONDITIONS OF THE STOMACH.

At a meeting of the Liverpool Medical Institution on March 22nd, a joint paper by Mr. G. C. E. STIMPSON and Mr. D. R. OWEN entitled "Some surgical conditions of the stomach" was read.

After a brief reference to congenital conditions, the authors stated that certain simple conditions of the stomach gave rise to symptoms and x-ray appearances closely resembling those of ulcer or cancer. In one case in which the symptoms had lasted for eighteen months and the x-ray indications suggested gastric ulcer, a fish-bone was found in the lesser omentum; in another case a fibroma of the lesser curvature was present. Illustrations

were given of wasting associated with marked filling defects which was due to fibrosis, papillomata, or the pressure of tumours outside the stomach. In yet another case fibrosis in the line of traction of the omentum adherent to a hernial ring had involved the outer coats of the stomach, giving rise to an hour-glass condition without an ulcer. Phlegmonous gastritis was described, and lesser degrees of gastritis and duodenitis were mentioned as possible pre-ulcerative conditions. It was suggested that more prolonged treatment should be given to ordinary attacks of indigestion, and special attention should be paid to the teeth. If the condition resisted medical treatment or showed signs of recurrence further investigation was necessary, and in persons over the age of 45 such treatment should not be prolonged. A tendency in some families to ulcer was illustrated by three cases in one generation. As regards the relation of ulceration to cancer it was stated that in only three cases had such an etiology been detected. The various methods of surgical treatment of simple and hour-glass ulcer were considered and cases were described. A posterior gastro-enterostomy with infolding or excision of the ulcer was thought most suitable for ulcers near the pylorus. Kammerer's method of gastropasty had been employed for hour-glass contraction with no active ulcers. It was thought that when skilled assistance and nursing were available, partial gastrectomy for ulcers on the lesser curvature or situated posteriorly was the best operation, since unpleasant sequelae were rare and the operation was often less difficult than that of freeing a penetrating ulcer by means of excision, suture, and gastro-enterostomy. Reference was made to a case of hour-glass stomach with a meso-colic hernia. Two other cases were recorded as being related to meso-colic hernia; in one the apex of the duodenal-jejunal flexure was pressing through the meso-colon, and had formed a kind of diverticulum in the lesser sac, and in the other a one and a half inch posterior gastro-enterostomy was found to exist without there being any abdominal scar. In the latter case it was uncertain whether there had been an ulcer of the the jejunum, or a condition of the the stomach. In carcinoma the advanced nature of the cases when seen by the surgeon was cited as an argument against the prolonged medical treatment of indigestion in later life. In advanced cases, exploration, or even a palliative operation, was a serious matter, but was to be commended in view of the fact that the diagnosis was sometimes wrong and a growth amenable to surgery might be found. The survivors justified taking the risk in cases which appeared to be hopeless. One patient survived for twenty-two months after a gastro-enterostomy; another was alive and well seven years after gastro-gastrostomy and gastro-enterostomy for carcinoma, confirmed by sections of the gland. In another patient, who was rapidly going downhill, a four-inch malignant papilloma was found to be invaginating the stomach wall, and six other papillomata were present; a year later, however, the patient was still alive and grateful for the relief. It was stated that in early cases partial gastrectomy by Polya's method was used, the posterior abdominal glands being removed as completely as possible; several cases were recorded in which apparent cure had resulted. Only one case of sarcoma had been encountered; this occurred three months after partial gastrectomy and proved rapidly fatal.

### CYSTOSCOPY IN CARCINOMA OF THE CERVIX.

At a meeting of the North of England Obstetrical and Gynaecological Society at Liverpool on March 16th, Dr. A. A. GEMMELL (Liverpool) read a paper on cystoscopy in carcinoma of the cervix based on a study of 111 cases of this disease.

Dr. Gemmell described the method employed to determine clinically the operability of these cases, and showed how cystoscopy added "sight" to "touch" in estimating anterior extension. The appearances seen were described in their order of gravity as being: (1) bulging of the bladder floor; (2) circulatory changes; (3) transverse ridging; (4) oedema, diffuse or bullous; (5) desquamation; and (6) malignant invasion, ulcerative or hypertrophic.

Other changes, seen more rarely, were also mentioned. It was insisted that the lesions were not pathognomonic of carcinoma of the cervix, but were important when seen just behind the trigone. Dr. Gemmell mentioned that all his cases had been checked by pathological examination of the growths. In a few cases in which it had been possible to repeat cystoscopy the order of severity of appearances mentioned had been confirmed. The bladder symptoms of the patients had been investigated, and it was shown that in both operable and inoperable groups approximately 50 per cent. of patients had no urinary symptoms, while 30 per cent. complained of frequency. This was taken to indicate that bladder symptoms were no guide to the degree of bladder involvement. The bladder appearances in the operable cases (39) and in the inoperable (72) were described. Five cases, clinically classed as operable, but by cystoscopy classed as inoperable, were found on further investigation to be inoperable. Out of 7 borderline cases, 5 were submitted to operation only because the cystoscopic findings were favourable; the after-histories of these cases justified the intervention. It was concluded that early transverso ridging was the appearance which denoted the limit of operability. It was shown that the appearances of the ureteric orifices were no guide to the difficulties likely to be encountered in their dissection, and catheterization of the ureters was recommended for this purpose. A manoeuvre was described for proving that the bladder was not adherent to the cervix. Prior to the introduction of the cystoscope a volsellum forceps was attached to the cervix; while the retrotrigono was being inspected traction was put on these forceps. When there was no attachment between the cervix and the bladder the former was seen to slide behind the latter; where attachment was present the bladder became wrinkled. The pathology underlying the bladder appearances was discussed, and figures were quoted suggesting a connexion between the cystoscopic appearances and prognosis of duration of life of the patient.

The PRESIDENT commented from his personal experience on the value of cystoscopic examination as an aid to the diagnosis of operability in cases of carcinoma of the cervix. Mr. R. KENNON (Liverpool) alluded to the observation that with the cystoscope early adhesion to the bladder could be detected by following the movements of the cervix, reacting to the drag on a volsellum forceps. He added that so simple a sign should be of wide application and value. Transverso ridging and bullous oedema, if in the retrotrigonal area of the bladder, had a grave significance. Professor MILES PHILLIPS (Sheffield) said that he had found the cystoscope of great value in these cases, and agreed that the ridge and furrow appearance indicated that the limits of operability had been reached. Mr. F. A. G. JEANS (Liverpool) concurred in the view that the appearance of the ureteric orifices was no guide as to the condition of the ureters in relation to extension of the growth.

#### *Abdominal Haematoma.*

Dr. K. V. BAILEY (Manchester) described a case of haematoma of the abdominal wall. The patient, aged 50, was a swimming instructress. During a fit of coughing she suddenly felt a severe cutting pain in the lower abdomen localized to a small area in the suprapubic region. She had no nausea or vomiting, but there was acute tenderness localized to the area where the pain was felt. No abnormality could be detected in the pelvis. At an operation both recti muscles were found to be densely infiltrated with blood along the greater part of their length from the pubes to the umbilicus. The site of the rupture was found on the under surface of the right rectus muscle, three inches above the symphysis.

#### *An Uncommon Foetal Attitude.*

Dr. J. W. BURNS (Liverpool) described a case of pregnancy in which there was an unusual attitude of the child in the uterus prior to the onset of labour. The patient had had five normal labours. Throughout the present pregnancy there had been, from the thirtieth week onwards, a marked disposition on the part of the foetus to change its position frequently. At the thirty-ninth week it lay transversely, with the head in the right iliac fossa. External version was tried, but it was found impossible

to move the head out of the iliac fossa. Attempts to push the breech up towards the fundus resulted in the breech rotating forwards; it could be brought over to the right side, but returned to its original position at once. An x-ray examination showed the child lying with its head hyperextended, the thorax over the brim of the pelvis, and the arms behind the back. The trunk was extended, and the thighs were extended with the legs flexed at the knees, so that the feet approached the occiput. Delivery was by Caesarean section.

#### *Ovarian Sarcoma Accompanied by Metrorrhagia.*

Dr. A. GOUART (Leeds) described a case of sarcoma of ovary associated with metrorrhagia. The patient, who was 65 years old, had reached the menopause twenty years previously. There had been some irregular haemorrhage for six months before she consulted him. A hard movable mass was found lying in the pouch of Douglas; at the operation this proved to be a solid tumour of the ovary. There were no adhesions. The whole uterus, which was removed with its appendages, was definitely enlarged with thickened walls, and the endometrium was quite one-eighth of an inch in thickness. The ovarian tumour was yellowish-white in colour, with a brain-like appearance and some ill-defined yellowish portions. Microscopically it proved to be a spindle-celled sarcoma with a few mitotic figures. Sections of the uterus showed the endometrium with well-formed glands, which penetrated a considerable distance into the muscle. The special feature of the case was the irregular bleeding long after the menopause and the unusual condition of the endometrium, which suggested that possibly the tumour had produced some hormone activating the endometrium.

#### *Torsion of a Hydrosalpinx.*

Mr. A. LEYLAND ROBINSON (Liverpool) showed a specimen of torsion of a hydrosalpinx removed from a multiparous woman, aged 48, who was the mother of seventeen children, two of whom had been born before menstruation commenced. For twelve months she had complained of irregular and somewhat excessive menstrual bleeding, and for nine months had been subject to paroxysmal attacks of pain in the lower abdomen, chiefly on the right side; this pain, which was colicky in character, was increased by constipation and relieved by purgatives. On examination the patient was found to have a tender, fixed right appendage swelling. At the operation the left tube was found to be closed, and contained a small quantity of clear fluid; the right appendage was lightly adherent to the rectum and back of the uterus, and at first sight appeared to be a small twisted ovarian cyst. On closer examination, however, it was found that the ovary was quite separate from the tube and was not involved in the torsion; what had been taken for a cyst was the distal portion of the tube, closed and distended with extravasated blood. Mr. Leyland Robinson added that, although torsion of the tube was common when the latter formed a part of the pedicle of a twisted ovarian cyst, primary torsion of the tube proper was rare.

#### *Torsion during Pregnancy of a Fallopian Tube and Ovary.*

Mr. J. E. STACEY (Sheffield) showed a specimen of torsion of a tube and ovary during pregnancy. The patient, during the fourth month, was suddenly seized with an acute agonizing pain in the right iliac fossa and back, which came on while she was at rest. She vomited, but did not faint, and there was no vaginal bleeding. Bimanual examination revealed a tender swelling behind and to the right of the pregnant uterus. A diagnosis of combined intra- and extra-uterine pregnancy was made. At the operation the right tube was found to have undergone torsion through 360 degrees, carrying with it the broad ligament and ovary. The tube and ovary, the latter containing the corpus luteum of pregnancy, were removed. The pregnancy went to term. After reviewing the literature on the subject, Mr. Stacey remarked that only three previous cases of this condition had been reported as occurring during pregnancy, and that all went on to term after removal of the tube and ovary. This fact was of special interest in the present case in view of the fact that the corpus luteum of pregnancy was also removed.

## Reviens.

### FRENCH TEACHING IN PUBLIC HEALTH.

AN important treatise has recently occurred in the French public health world—the issue of two large volumes setting out the lectures on public health given at the Institute of Hygiene of the Paris Faculty of Medicine by some thirty-eight teachers, under the direction of Professor LÉON BERNARD, professor at the faculty and a technical adviser to the Health Ministry, and M. ROBERT DEBRÉ, assistant professor at the faculty and a physician of the Paris hospitals. The names of some of the writers are already well known in this country. Thus Professor Bernard, who writes most of the text on tuberculosis, represents France on the Health Section of the League of Nations; other familiar names are those of Professor E. Brumpt, who writes on relapsing and yellow fevers; M. H. Vallée, honorary director of the National Veterinary School at Alfort, whose collaboration is, unfortunately, limited to anthrax; Dr. Jules Renault, technical adviser to the Ministry of Health, who deals with the sanitary defence of land frontiers; Dr. Henry Pottevin, director of the Office International d'Hygiène Publique, who was the obvious person to write on international sanitary conventions; M. E. Saquépée, Médecin Inspecteur de l'Armée and professor at Val de Grâce Hospital, who writes on food poisoning; M. R. Sabouraud, who deals with ringworm; and M. E. Rolants, whose work on activated sludge is so well known, writes on sewage and trade wastes.

A considerable part of the volumes is from the pen of M. Ch. Dopter, who deals with general epidemiology and the prophylaxis of several of the individual diseases—bacillary and amoebic dysentery, pneumonia, influenza, diphtheria, and tetanus. His writing is marked throughout by clarity of style, simplicity of diction, and excellent arrangement of matter. An interesting point he brings out is the wholesome influence of the various constituents of pure wine (and especially the acids) in destroying typhoid bacilli; evidently any contamination of wine by typhoid sufferers or "carriers" is relatively harmless. White wine is even safer than red in this respect. As might be expected, the text on food is both full and adequate: the consumption of a large number of species of edible fungi in France is reflected in the section by M. H. Martel, director of the veterinary services of the Department of the Seine. The extent to which the collaboration of the veterinary profession has been sought is much to be commended. The French people, who at one time had a rooted objection to the use of any other than fresh meat, have been forced by economic changes to have recourse to frozen and chilled meat; they will obtain a good deal of comfort from reading the praise of chilled meat by M. Nicolas, director of the National Veterinary School at Alfort. There is much useful information to English hygienists in his section and in that on the preservation of food by cold, written by Dr. Lortat-Jacob, a vice-president of the French Cold Storage Association.

*Sans enfants aujourd'hui, plus de France demain!* Those arranging the course kept this aphorism well in the foreground, and adequate space is given to the baby and his protection. M. E. Lesné, physician to l'Hôpital Trousseau, writes ably and in considerable detail on the feeding of infants and very young children, and on the protection of healthy and unhealthy children. The safeguarding of motherhood receives adequate attention from the obstetrician Professor A. Couvelaire, but the consideration of school hygiene is tacked on to the section on the social hygiene of the infant, a paltry eighteen pages or so being devoted to this important subject.

For the text on the hygiene of occupation (283 pages), written by M. Marcel Frois, Inspector-General to the Ministry of Labour, M. M. Duvoir, an assistant professor and physician to the Paris hospitals, and M. E. Kohn-Abrest, director of the Paris laboratory of toxicology, it is difficult to find anything but praise; though some

slight repetition might perhaps have been avoided. The chapters on water (M. P. Diénert, the chief of the Paris water department), on sewage and trade wastes, and on housing (M. Edouard Arnaud, the chief Government architect) are quite equal in standard to the rest of the book, and the illustrations here are decidedly helpful. Two figures depict activated sludge installations at Davyhulme and Withington, when the air is blown into the sewage. M. Rolants is able to include a diagrammatic representation of a French installation (at Mesly) where the air is slapped into the sewage by paddles, as at Sheffield. Vital statistics are treated in a somewhat novel manner by M. Yves Biraud, chief statistician to l'Institut d'Hygiène, who by the use of diagrams makes his text much clearer to non-medical readers. Professor Bernard concludes with a very interesting chapter on the relation of the medical profession to public health.

The editors have certainly succeeded on the whole in presenting a course of uniform teaching with but very little repetition. Certain of the lectures, notably the one on the feeding of the infant, are set out in an admirable way, the separate divisions of the subject being adequately distinguished by cross-headings in the right-sized capitals, a feature of considerable value in a book which must largely serve as a work of reference. But the collaborators are apt to give scanty references; there are a few foot-notes to some of the sections, but no real attempt at a bibliography. These volumes bring out the well-known fact that the organization of public health in France is far behind that of this country, but they also show that as scientists and writers our French colleagues can rival the best of other nations.

### UROLOGY AND SYPHILOLOGY.

DR. C. H. CHETWOOD'S *Practice of Urology and Syphilology* has reached its fourth edition, a fact which by itself testifies to its popularity. In the new edition many alterations will be found, among others a change of publishers. As the author says in his preface, since the appearance of the preceding edition unmistakable progress has been made in urology. He is indeed of the opinion that the last five years have been more fruitful in innovations and discoveries than any corresponding period since his book first appeared. He cites, as examples, the introduction of new internal and local antiseptics, notably hexyl-resorcinol, acriflavine, and mercurochrome. Diagnostic methods, such as pyelography, have also been developed, and the use of diathermy as a means of treatment has extended. All these improvements receive adequate attention in the new edition.

In prostatic surgery the importance of pre-operative and post-operative treatment has received wider recognition; and the portions of the book dealing with these matters have been amplified. Dr. Chetwood, himself a pioneer in the method of treating contracture of the bladder neck, pays due attention to this important subject. However, he does not appear to be convinced that the various perurethral means of treating this disease are of necessity the treatment of choice. In his opinion open operation and division of the contracture by means of scissors gives better results in some cases. He therefore sounds a note of caution on the subject, giving it as his opinion that "the end-results following the different operations have been of variable success in the past, and must be observed over long periods to estimate correctly the comparative advantages of both open and closed operations." It is perhaps a pity that he has not given a description of the perurethral methods that have been introduced for the treatment of this condition, since many of his readers are unfamiliar with such instruments as the cautery punch, the diathermy punch, and Collings's diathermy knife.

The second part of the work is devoted, as before, to syphilology. Custom has ordained in the past that syphilology should be considered a branch of urology. In the future, perhaps, the association of urology and syphilology

<sup>1</sup> *Cours d'Hygiène*. Sous la direction de Léon Bernard et Robert Debré. Tome I et Tome II. Paris: Masson et Cie. (Sup. roy. 8vo, Tome I, pp. ix + 1247; illustrated. Tome II, pp. 811; illustrated. 160 fr.; sans majusculation.)

<sup>2</sup> *Practice of Urology and Syphilology*. By Charles H. Chetwood, M.D., LL.D., F.A.C.S. Fourth edition. London: Milford, Oxford University Press, 1928. (Med. 8vo, pp. xii + 873; 314 figures, 11 coloured plates. 42s. net.)

may be less intimate. At any rate there is a distinct disadvantage in including such a subject as syphilis of the central nervous system within the province of the urologist. But primarily Dr. Chetwood's book is a work on urology, and it is by the first rather than by the second part of it that it must be judged. On some future occasion the advisability of expanding the urological sections and eliminating those dealing with syphilis, other than syphilis of the genito-urinary tract, may be considered.

The book is well illustrated and contains many excellent coloured plates. It is seldom that an American author chooses an English firm as his publisher, and it is gratifying to know that when such a choice is made the results are excellent.

#### MEDICAL PROTOZOOLOGY.

*An Introduction to Medical Protozoology*<sup>1</sup> is a sequel to Lieut.-Colonel R. Knowles's *Lecture Notes in Medical Protozoology* of 1923—a much smaller volume now out of print. It is intended primarily for the author's own students in India, but he hopes it will be of use to laboratory workers in other parts of the world. He has drawn on Wenyon's *Protozoology* for much of his material, but his own volume had been planned and commenced before Wenyon's appeared. Other standard textbooks have also contributed their quota, and all are freely acknowledged by Colonel Knowles in his preface. The volume is divided into three parts—Part I (626 pages) dealing with systematic protozoology, Part II (144 pages) with laboratory methods, and Part III with literature. Part I is divided into nineteen "lectures" and Part II into seven "chapters"—a somewhat confusing nomenclature, particularly as the pagination is continuous throughout. The lectures—which must make note-taking in India a strenuous undertaking—consider all the groups of the protozoa parasitic in man and animals, together with the spirochaetes, rickettsia bodies, and the Chlamydozoa. Part II considers apparatus, microscopic technique, culture methods, dissection of insect hosts, and so on. The whole volume is excellently illustrated with text-figures and coloured plates, many of them original. That the volume is a valuable one there is no doubt, but its conception does not seem to be above criticism. It is admittedly more comprehensive than is necessary for a school textbook; it is hoped that this will increase its extramural circulation. As a volume of reference, however, it cannot take the place of Wenyon's classical production, although it has the advantage of being very much cheaper. Its value seems to lie mainly in the appeal it is bound to make to the advanced student of medical protozoology, an appeal which is strengthened by the detailed chapters on technique. It should also be a valuable textbook to the isolated worker in the tropics who requires a more comprehensive knowledge than is given in an ordinary course of lectures, but who does not wish to have the detailed information of the specialist.

#### VENOUS CONGESTION AND PERICARDIAL EFFUSION.

In a monograph entitled "Congestion types in circulatory disturbances"<sup>2</sup> Drs. HERBERT ELIAS and ADOLF FELLER of the Vienna school report a series of clinical, anatomical, and experimental observations undertaken to find some explanation for the variations in the clinical picture of venous congestion, with special reference to that associated with exudative pericarditis. According to their findings three stages of congestion may be recognized in pericarditis with effusion. (1) It begins with a rapid and great enlargement of the liver, slight cyanosis, no oedema at first, but later with ascites; when the patient takes to bed there is a transient facial oedema. (2) Cyanosis increases, and facial oedema returns and persists, the

liver grows in size, while pulmonary congestion is relatively slight. (3) Cyanosis becomes extreme and generalized oedema develops. Examination of hardened preparations from cases of pericarditis, artificial effusions in the cadaver, corrosion preparations, etc., leads to the conclusion that these three clinical stages correspond to anatomical stages of effusion. (1) A small effusion, which collects caudally in the caval portion of the pericardial sac, causes a conspicuous narrowing of the mouths of the liver veins in addition to a slight compression of the inferior vena cava; this compression is relieved in the recumbent position, as then the fluid lies more dorsally and towards the head, and may narrow the mouth of the superior vena cava. (2) A larger effusion greatly compresses the inferior cava and the lower auricular segment, and increases the narrowing of the liver veins. (3) A very large effusion under high pressure so compresses the right auricle that the walls come together; because of this obstruction the tributary veins are not narrowed but dilated.

The authors appear to have spent much time and labour on their thesis, which is well put together and well illustrated. Their conclusions, however, would have been more satisfactory had more direct clinical evidence been included—as, for example, measurements of the venous pressure in their patients during life.

#### LABORATORY MANUALS OF BACTERIOLOGY.

Dr. H. J. CONN, one of the joint authors of Conn's *Bacteriology*, has compiled a small handbook entitled *An Elementary Laboratory Guide in General Bacteriology*,<sup>3</sup> to be used in the practical bacteriology class. The eighteen exercises are well arranged to give instruction in the general methods which constitute the foundations of bacteriological technique, but they are not sufficiently comprehensive to cover the instruction given to medical students or students of public health. It is an excellent introduction to the principles of bacteriology.

The authors of the handbook *The Principles of Practical Bacteriology*<sup>4</sup> have addressed themselves to the growing company of non-medical scientific workers who wish to obtain some training in the science of bacteriology. The information provided could only be properly assimilated by a student actually performing these exercises, and if used as a manual for a practical class this little book might be useful. It is not suitable for the training of the medical student of bacteriology.

Judging from the punctuality of the appearance of new editions, of which there have been twenty-eight in the last thirty-eight years, *Bakteriologisches Taschenbuch*<sup>5</sup> is a favourite with the German-speaking medical student. It certainly has an astonishing amount of information crammed into its 166 pages, and its modest claim of "pocket-book" is well deserved, since it is not much larger than a pocket diary. There is a good index, and references are given to a fair number of original articles when new work is recorded.

Dr. MAX LEVINE, in his little book *An Introduction to Laboratory Technique in Bacteriology*,<sup>6</sup> describes seventy-six exercises to be performed by a student in the practical bacteriology class. These vary from the preparation of media to the agglutination test. Though the exercises are well chosen and adequately described, it is doubtful if the book in its present form is likely to be of use to the medical student of bacteriology, because it contains many exercises that would be of no interest to him, and omits others necessary for his training.

## PSYCHIATRY FOR NURSES.

Dr. ARTHUR P. NOYES's *Textbook of Psychiatry*<sup>9</sup> represents the results of an experience of several years lecturing on psychiatry to students of Saint Elizabeths Hospital Training School for Nurses at Washington and to members of other training schools of nursing. There is a real demand for such a book as this, specially designed for the use of the nursing profession, for the ordinary textbooks on mental diseases are too technical and elaborate for nurses' use. Dr. Noyes gives a skillful presentation of his subject. He deals with the structure of the mind, mental mechanisms, and the nature and causes of mental disease in unequivocal phraseology, availing himself largely of the results of psycho-analytic teaching. The classification of mental diseases is discussed, and the psychoses are dealt with serially. The chapter on manic-depressive psychoses not only gives a clear picture of the various forms of this syndrome, but contains much wise practical advice. Dementia praecox is treated fully, and here again the nursing hints given are particularly valuable. An adequate account of the blood and cerebro-spinal fluid in cases of general paralysis supplements the description of the neurological and mental condition in that disease. There is a short chapter on mental deficiency. The care and management of the mental patient are discussed, and the relationship of nurse to patient is understandingly handled. Bibliographical references supplement each chapter, and in addition many books and pamphlets are quoted for the benefit of those who desire a more extended knowledge of psychiatric literature.

In *Nursing Mental and Nervous Diseases*<sup>10</sup> Dr. A. C. BUCKLEY has presented his subject along much the same lines as in his well-known book *The Basis of Psychiatry*. The method, so successfully employed in that book, of presenting the subject of mental disorders from the standpoint of general biology, serves here to provide the nurse with a clear understanding of the groundwork of her subject. Dr. Buckley remarks that among mental disorders there is a relatively large number which, medically considered, are in the same class as bodily illnesses, and that if this fact were more widely recognized the present-day artificial distinction between mental disease and bodily disease would disappear. He does not ignore, however, the distinctions that arise in the nursing of these two classes of illness, but stresses the very special attention that must be given to mental patients on account of the alteration of behaviour. Detailed instructions are given with regard to the special feeding procedures required in certain cases. The methods of promoting sleep are described, and much is said about the necessity for the elimination of waste products in these cases. There is a serviceable account of the various psychoses, and one section of the book is devoted to a description of the diseases of the nervous system. Special therapeutic methods are described at length; these include various hydrotherapeutic measures, all of which are fully illustrated. This book is a welcome addition to Lippincott's Nursing Manual Series.

## THE FAITH OF A SCIENTIST.

The first of the series of lectures provided for by the Halley Stewart Trust were given by Sir OLIVER LODGE in the year 1926, and have now been published in a book entitled *Science and Human Progress*.<sup>11</sup> It will be remembered that the object of the founder of the Trust was the encouragement of clear thinking in the realm of religion and education, as well as to encourage charitable enterprises beneficial to the community. Sir Oliver Lodge, in his opening lecture, began by assuming that the founder of the Trust designed that it should be "free and open and unhampered by restrictions such as may at any time become out of date—a living Trust, ready to be adapted

and utilized in accordance with the necessities of the time." This assumption, one obviously in keeping with the spirit of the foundation, has encouraged Sir Oliver Lodge in these six lectures to survey the whole universe and comment in philosophic vein on the aims and development of mankind, the relation between theology and science, the problem of survival after death, and other mysteries of our existence. In these territories, however, he only pauses for a moment, and he is soon off again to the recurring motive of every lecture—the invisible spirit population of the universe. On this subject he is often eloquent, as in the following passage (p. 61):

"Evidence is accumulating that humanity as a whole is not isolated in the universe, as it used to think it was, but that we are in close and affectionate touch with a higher order of beings, who realize our difficulties, help our struggles, and who, recognizing the vital importance of this earthly period of existence, are straining their faculties to the uttermost to step in wherever they are given the opportunity—not by force, not with any compulsion, but by permission, by good will, or in response to entreaty—so that, by co-operating with us, they can contribute to the advancement of the whole."

## NOTES ON BOOKS.

ALTHOUGH the medical profession has produced many poets, some of them numbered among the immortals, it is difficult to say offhand why this should be so, for there is no apparent connexion between poetry and medicine. Some, like Keats and Robert Bridges, may have entered our profession without any strong leaning towards its practice, and soon afterwards devoted themselves with single mind to the Muses. Others at the end of a busy week's work find recreation in the writing of verse as an escape from the hard realities of the medical life. Others, seeking an outlet for the gift of expression, weave medical thoughts and experiences into a metrical pattern. Among the third group a place could certainly be claimed by Mr. BISHOP HARMAN, even though the professional items in *To-day, and Other Verses*<sup>12</sup> are relatively few in number, and it would, we think, be more correct to say that at heart he belongs to the second. If the themes touched on in this daintily produced volume are here and there a little pedestrian, and better suited to prose than verse, the author's range of subject and metre is wide, his pen moves with enviable freedom in very diverse moods, while the sincerity of his feeling and his broad humanity can be felt on every page.

The growth of population in most European countries may be expected to lead to the exploitation of countries hitherto little known, and Mr. HENRY M. GREY, in an interesting account of a 1,500-miles trek on mule-back through the swamps and forests of Eastern Bolivia, describes that country as *The Land of To-morrow*.<sup>13</sup> Its natural resources are numerous. Gold, copper, tin, and petroleum occur in easily worked forms, while the rich earth readily grows cocoa, coffee, cereals, cotton, and tobacco. Tropical and subtropical fruits are plentiful, rubber grows wild, and, in parts, there is rich and abundant pasture for cattle. The disadvantages of the country are, however, numerous; the temperature in the localities visited ranged from 50° to 100° F. in the shade, but the author was there only in the cold season. He describes the climate in some places as "ideal." Dangerous wild animals are scarce, but the "minor horrors" appear to be abundant. Owing to the numerous swamps mosquitos abound, and malaria is common. Ticks, tarantulas, vampire bats, jiggers, "mosquito-worms," large black ants, and snakes—including the anaconda and boa-constrictor—were met with during the trek, and some rivers are infested with fishes which render bathing dangerous. In addition to the sting-ray, two fishes of particularly objectionable habits were noted: the *peraiia* delights in biting off the fingers, toes, or other projecting parts of the bather; while the *handeroo*, about one inch in length and no thicker than a match, may dart into any natural orifice of the body, whence it is difficult to dislodge. The rivers also abound in *jacares*, or small alligators. Bands of savages, armed with bows and arrows, spears and clubs, raid the dense forests, and are responsible for many murders and the brutal mutilation of travellers. The arrows and spears are poisoned with curare, which is prepared in secret by the chiefs and "medicine men." The author states frankly that he is not a naturalist, the object of his journey being to report on a rubber estate, and his comments on the prevalent diseases are naturally not of great scientific value. Although malaria is found in the vicinity of

<sup>10</sup> *Nursing Mental and Nervous Diseases*. By Albert Conlson Buckley, M.D. London: J. B. Lippincott Company. 1927. (5½ x 8½, pp. 312; 57 figures. 12s. 6d. net.)

<sup>11</sup> *Science and Human Progress*. By Sir Oliver Lodge. London: George Allen and Unwin, Ltd. 1927. (Post 8vo, pp. 187. 4s. 6d. net.)

<sup>12</sup> *To-day, and Other Verses*. By N. Bishop Harman, M.A., M.B., F.R.C.S. London: The Lindsey Press. 1928. (Cr. 8vo, pp. xii + 136. 5s.)

<sup>13</sup> *The Land of To-morrow*. By Henry M. Grey. London: H. F. and G. Witherby. 1927. (Demy 8vo, pp. 224; 6 plates, 1 map. 12s. 6d. net.)

the numerous swamps, enteric, cholera, and yellow fever are apparently unknown. Beri-beri is common, and the death rate from this disease varies from 2 to 50 per cent. according to the locality. The author himself contracted the disease, and attributed the cause to eating rice, as bread was rarely obtainable. Venereal diseases are said to be rife among the natives in the interior, having probably been introduced by European traders. A great drawback to the exploitation of this fertile country is lack of transport. The railway is gradually creeping north from the Argentine, but had made little progress at the time of the author's visit, the year of which is not stated, but it was shortly before the outbreak of the great war. Mules provided the chief means of transport, as the rivers, though numerous, are not navigable in the upper reaches, which alone flow through Eastern Bolivia. When the railway has extended beyond Santa Cruz, when roads suitable for wheeled traffic have been constructed, when the swamps have been drained, the rivers bridged, and the savage bands civilized, there awaits the planter and the miner a rich country. But before all its benefits can be realized there is work for the advisory expert in tropical hygiene.

*Black's Veterinary Dictionary*<sup>14</sup> is the inevitable companion to the same publishers' medical dictionary. It is modelled on the same plan, and is printed and published in a similar form. It provides a ready work of reference for all who own animals, and it should be a useful volume for those who practise human medicine. In straightforward, almost non-technical, language it explains all that the animal owner requires to know about the diseases which affect his stock, and it explains these on a rational basis—that is, anatomy and physiology precede the merbid discussions. It also provides a satisfactory manual of first aid for animal diseases, but it in no way attempts to make "every man his own veterinary surgeon"; rather it encourages the employment of skilled aid where necessary, and explains why and when this is required. Besides the purely practical part of the dictionary there are numerous fairly lengthy articles on genetics, diet and dietetics, parasites and parasitology (an article very fully illustrated with text-figures), and breeds of live stock (with numerous plates of typical animals). The book is edited by Mr. W. C. MILLER of the Royal (Dick) Veterinary College, Edinburgh, and the articles referred to above (among others) have been contributed by specialists in these branches. A volume such as this does much to explain the present standpoint of veterinary medicine, and to dispel the old idea—which still lingers here and there—that it is a purely empirical art. Those who use this work will realize that there is only one science of medicine, and that its application to animals is based on the same general principles as its application to man; the technique only differs. The price of the dictionary is remarkably low when one considers its size—over 1,000 pages and 400 illustrations—and the excellence of its production. It should accordingly prove of great value and importance, not only to the animal owner, but to the student and practitioner of human and veterinary medicine.

*Lee's Microtome's Vade-Mecum*<sup>15</sup> requires no introduction as the standard work on microscopical technique, and the ninth edition, edited by Professor BRONTÉ GATENBY and E. V. COWDRAY, will doubtless receive a very warm welcome. The embryological, psychological, protozoological, and entomological sections have been revised and enlarged, and new sections have been introduced. Special attention has been paid to the index, and, as in previous editions, the information is set out with exemplary clearness. It would be difficult to praise the book too highly.

*Immortality*,<sup>16</sup> the title of a small book in which this subject is philosophically treated by Dr. I. HARRIS, is of interest to all men. This is not the first time that a physician has expressed his views thereon; twenty-four years ago Sir William Osler gave at Harvard "The Ingersoll Lecture on the Immortality of Man," entitling this charming but short address "Science and immortality." Dr. Harris believes that science can provide the material for a creed which will act as a living pulsating force for all sections of the community.

The first issue of *Who's Who in the Nursing World* is intended to supply to the nursing profession and general public particulars of administrative and examining bodies, the nursing services, nursing associations, institutions and societies, nurse

training schools, clubs and journals, and a list of prominent persons in the nursing world, which will probably receive considerable additions in subsequent years. It should prove a useful work of reference. The only important omission we have detected is the absence of any mention of the hospitals of the Metropolitan Asylums Board among the London fever hospitals.

Those who have learnt to rely on the Union Castle Mail Steamship Company's *South and East African Year Book*<sup>17</sup> as a guide to any and every aspect of life, work, and transport in South and East Africa will welcome the appearance of the thirty-fourth issue at half the price of former years. The section on health and climate affords, as usual, information as to the facilities available for invalids. It is a pity that the recent suspension of the issue of permits for the entry of tuberculous patients into the Union—a matter of considerable importance—is not noted under this head at page 85 as well as under "Immigration" at page 191.

<sup>14</sup> *The South and East African Year Book and Guide*. Edited by A. Samler Brown, F.R.M.S., and G. Gordon Brown, F.R.G.S. Thirty-fourth edition. London: Sampson Low, Marston and Co., Ltd. 1923. (Cr. 8vo, pp. iv + 919; 32 maps. 2s. 6d.)

## PREPARATIONS AND APPLIANCES.

### A LOOP FOR MEASURING THE BLOOD COAGULATION TIME.

PROFESSOR O. S. GIBBS, M.B. (Dalhousie University, Nova Scotia), writes: In 1924 I described an instrument for the accurate and convenient measurement of the coagulation time of human blood.<sup>1</sup> This instrument consisted essentially of a 5 mm. platinum wire loop, on which is formed a bead of blood, which, on being warmed to body temperature by placing the instrument in a basin of warm water, runs freely on the wire, stopping, however, very sharply when clotting takes place. In order to form the bead of blood the loop was cut through in one place, which weakens it considerably, and thus renders it liable to be distorted on being used. Recently I have found that if in place of the actual gap a virtual gap is made by a small indentation in the wire at right angles to the plane of the loop, this functions equally well, and the loop is far stronger.

I have received several complaints that my results could not be confirmed. In every case the cause of the trouble has been the use of an improper loop, this being either too small or, more frequently, made of too thick wire, which should be No. 31 or No. 32 B.S.W.G. (usually the size supplied for chemical flame tests). Further experience with this method has confirmed my original results. For animal work reference may also be made to a second paper on this subject.<sup>2</sup>

This instrument is now obtainable from Messrs. C. F. Palmer, Myographic Works, Brixton, London, S.W.2.

### IRRADIATED ERGOSTEROL.

"Vigantol" is a preparation of irradiated ergosterol accurately standardized and prepared by I. G. Farbenindustrie A. G. (Pharmac. Dept., Bayer-Meister Lucius) and E. Merck of Darmstadt. It is sold in this country by H. R. Napp, Ltd. (3 and 4, Clements Inn, Kingsway, W.C.2). Irradiated ergosterol is believed to be identical with vitamin D, and the preparation is intended for the prevention and treatment of disturbances of bone formation. "Vigantol" is sold in liquid form (1 per cent. solution in oil; dose 5 to 10 drops daily), and in sugar and chocolate-coated tablets containing 2 and 4 mg. of irradiated ergosterol respectively. The vendors claim that the preparation has given excellent clinical results. It possesses a pleasant flavour, and the makers estimate that the 2 mg. tablet is equivalent in vitamin D content to more than a tablespoonful of cod-liver oil.

### DIMOL SNUFF.

The Dimol Laboratories, Ltd., have produced an insufflation powder for the prevention and relief of nasal catarrh. This antiseptic snuff is sold in glass tubes, and medical practitioners can procure ebonite containers in the shape of a miniature wine bottle, with a slip-on neck and movable cone controlled by means of a spring. In use the neck is removed, the bottle inverted and tapped on the back of the hand. The price of this little distributor is 2s. 6d., and refill tubes of the powder are supplied at 1s. each.

### AN EMERGENCY BRANDY FLASK.

Martell's brandy flask should prove a handy addition to the medical emergency bag. It has a patent cap, which dispenses with the need for a corkscrew and can be replaced as often as necessary. The flask itself is shaped to fit the pocket, and an aluminium drinking cup, reaching half-way up the container, gives some protection against breakage. The flasks, as sold, contain Martell's three star brandy.

## NATIONAL HEALTH INSURANCE IN SOUTH AFRICA.

### SOME PROBLEMS FOR SOLUTION.

THE Government of the Union of South Africa has appointed a Parliamentary Commission to inquire into and report upon the questions of old age pensions, insurance against sickness and unemployment, and for widows and orphans. The Commission has concluded its investigations with regard to old age pensions, and is now engaged on those relating to the other matters which have been referred to it. It is understood that these other matters are not to be dealt with piecemeal, but are to be combined in one scheme of national insurance. It is improbable, therefore, that any scheme evolved can become actually operative for at least four or five years, but even now suggestions are taking form, and a provisional bill embodying some of these suggestions is in process of drafting.

The medical profession in South Africa, and indeed the whole of the British Medical Association, is vitally concerned with such of these proposals as relate to national health insurance, and though it may be premature as yet to come to a decision on certain important details—for example, the amount of the remuneration to be asked for such services as the profession may render, or the nature of any machinery for the investigation of complaints—it is now becoming a matter of some urgency for the profession in South Africa to make up its mind on certain broad questions relating to the general nature of the scheme. Indeed, the Medical Association of South Africa (British Medical Association) has been asked, somewhat insistently, by the Parliamentary Commission to keep it informed as to professional opinion on many important points. Answers to these questions must be forthcoming within the next few months if they are effectually to influence the opinions of the members of the Commission and the nature of their report.

### GEOGRAPHICAL AND RACIAL DIFFICULTIES.

It is clear that conditions in South Africa differ radically from those in Great Britain, or indeed in any other country which has adopted a scheme of national health insurance, and that therefore no existing scheme for such insurance could be applied to South Africa without the most fundamental alterations.

South Africa is a country of vast extent with a relatively small population, only a small proportion of which is of pure European descent. Considerable tracts may still be described as unsettled or of a strictly colonial character. In the remainder industrialization has not proceeded very far. A few industries are concentrated in a small number of areas, and the great mass of labour is poorly paid, being mainly native or coloured. Certain of the existing industries, such as the railways and the mines, have already established schemes for medical attendance and sickness insurance of a far-reaching and practically compulsory character. There seems to be nothing in South Africa corresponding to the Poor Law medical arrangements in England, but there are a number of "district surgeons" whose duty it is to respond to medical calls from those unable to pay any fee, provided that certain formalities are complied with.

It is thus evident that perhaps the most fundamental question to be determined is the extent of the working population which the insurance scheme should cover. Shall it be for the urban population only, rural areas being excluded? And, if so, what is to be the definition of a rural area? Shall it be for whites only, or for whites and coloured—natives, Indians, and Malays being excluded? Shall it include or exclude those employments which have already established adequate schemes for medical benefit? What should be the limit of income under which employees are insured persons, and should such limit apply to manual workers as well as to others?

Unfortunately there are no easily available statistics which would assist judgement on these matters, and it is certain that an all-embracing insurance scheme would involve administrative difficulties of a formidable, but not necessarily insuperable, character. Nevertheless, on general

principles it is clear that any scheme of medical benefit which did not apply to rural areas, or to the coloured or native population, would be open to the objection that it would meet the needs of those who required it least to the exclusion of those who required it most. The political complications, too, which might arise from any such proposals are by no means negligible.

The problem of the sparsely populated areas is in any case difficult, but there are certainly two methods by which it might be dealt with. It would be possible to schedule certain regions as in the unsettled or pioneer stage, and therefore outside practicable medical provision. Other regions which have advanced beyond this stage, but in which the scattered population, and the great distances which a doctor must travel to render service, make insurance actuarially impracticable, might be provided for apart from the insurance scheme, but simultaneously therewith, by some form of subsidy to medical practitioners (there are several such forms possible), somewhat on the lines of the Highlands and Islands arrangements in Scotland. In districts not scheduled under one or other of these headings the ordinary insurance scheme would apply, with, of course, a mileage fund in addition to the common remuneration in certain areas. Alternatively, it might be possible to define, in this respect, the persons to whom the insurance medical benefit would apply as those living within  $x$  miles of a doctor—again, of course, with a mileage payment to those practitioners travelling beyond a certain distance (less than  $x$ ) to visit their insured patients. The main difficulty of the latter suggestion would be found in the migrations of insured persons and of practitioners; but, in case it be adopted, it is an urgent matter for the profession to determine the appropriate value of  $x$ .

### EXTENT OF INSURED POPULATION.

The coloured people, as distinct from the natives, are concentrated in the Cape Province, where they have the parliamentary franchise and exercise much political influence. It would seem almost impossible to exclude them from medical benefit. Administratively it would not be so difficult to exclude the natives; but if this were done much of the social and public health value of the whole scheme would be lost. It seems probable that the question of colour will be avoided by not mentioning it at all, but by giving special consideration to the position of low wage earners. Such a class would include not merely most of the natives and coloured people, but also many of the class known as "poor whites," preponderantly low-class Dutch. It will be remembered that in the national health insurance scheme of Great Britain special provision as to premium is made for low wage earners. Whereas, however, in Great Britain this class comprises an almost inconsiderable number of persons, in South Africa it would include a very large number of insured persons if there is to be no distinction of colour. This must profoundly affect the nature of any insurance scheme, and a suggestion for dealing with the situation so envisaged may be worth considering.

The suggestion is this: that the main general insurance scheme should be established nationally on such a minimum basis, both as regards contributions (whether from employer or employed) and as regards benefits, as would meet the needs of the great mass of low wage earners; and that upon this minimum should be superimposed a compulsory industrial insurance for each of those industries which are sufficiently large and sufficiently organized to permit of it. The minimum scheme would, of course, include medical benefit, and this would have to be as good and as full for one class of insured persons as for another. Provided that none fell below the minimum, both contributions and other benefits might well vary from industry to industry (or, by agreement, even between different classes of workers within an industry), according to the needs of the case. Those industries which fulfilled the necessary conditions might be scheduled in the parliamentary bill embodying the scheme, and the Minister of Public Health might be empowered to add to the schedule other industries as, in the course of time and natural development, they arrived at a suitable stage. Administration in such cases would be by industry—in the ordinary case by locality—but there would probably have to be a

certain amount of interlocking of administration, inasmuch as certain functions might well be performed by the local administration on behalf of the industrial organization, especially with respect to outlying members.

Such a scheme would allow of the continuance of some existing provisions for medical and other benefits already working fairly satisfactorily in connexion with the railways and some mines, though modifications in detail might be necessary to bring them into conformity with the general scheme. It would also permit of provision being made for medical advice and treatment to the dependants of employees where this is one of the benefits already provided, or in other suitable cases. In a highly industrialized country such a scheme would present great difficulties, but it would not be inappropriate for South Africa. There are probably only four industries in that country which could be immediately scheduled as carrying contributions and benefits above the national minimum—the railways, the mines, the building trade, and the distributing trades (mainly shop assistants and warehousemen). Between them these include the majority of those who would become insured persons.

Under any national health insurance scheme, or any such combination of national and industrial insurance as that suggested, the question of an income limit for employees to be included at once arises. In Great Britain the income limit is £250 a year, and this applies to non-manual workers only, there being no limit in the case of manual workers. In South Africa a tentative suggestion has been made that the income limit should be £400 a year, but representatives of the medical profession have declared that this is much too high, and have expressed the opinion that any income limit agreed upon should apply to the whole of the insured population. This appears to be both logically and socially right, and has been proposed by the British Medical Association for Great Britain. Here, however, it is declared to be administratively and industrially impossible to apply an income limit to weekly wage earners. The conditions in South Africa seem to offer a more favourable ground for the experiment, which would be of great value if successful. The lower income limit of £6, or at most £7, a week has been mentioned as an alternative to £400 a year. This is one of the points on which the profession should come to a speedy decision, and it is obvious that reliable statistics of employment at various rates would be most helpful.

#### SCOPE OF THE MEDICAL SERVICE.

In the circumstances of South Africa the determination of the scope of medical advice and treatment to be provided should prove a less difficult problem than that of the extent of the insured clientele. There are three considerations which together should go far towards influencing a decision on this point.

(1) Experience in Great Britain has shown that the restriction of medical services to those which in the best interests of the patient can properly be rendered by general practitioners as a class not only materially lessens the public health advantages of the whole scheme, but also requires the formulation of a large number of regulations or rules which complicate the scheme and annoy many of those who participate therein.

(2) The line of demarcation in South Africa between what are commonly regarded as general practitioner services and real specialist services is peculiarly difficult to draw, partly owing to lack of specialist facilities over large areas throwing more responsibility on the general practitioner, and partly owing to the stage in the development of specialism within the profession which has at present been reached even in the larger towns.

(3) In the main schemes for medical treatment on a contributory basis which are now in operation in South Africa it is usual to include all kinds of medical services, even full hospital provision.

It thus appears desirable and feasible that any health insurance system established in South Africa should from the beginning make the medical provision much more complete than in Great Britain; and the medical profession might well advise the Parliamentary Commission in this sense, even though it be recognized that financial considerations must also be a factor in the ultimate decision.

#### FURTHER PRACTICAL QUESTIONS.

If, then, a health insurance scheme be postulated which includes a large proportion of the working population and has regard to the requirements of the low wage earner, and in which various classes of medical practitioners may participate, there still remain several important questions relating to the form of contract and the methods of providing medical attendance; and these the medical profession may reasonably be asked to answer at an early date. Broadly, they may be stated as follows. Should the Government make a contract for medical services with the organized profession as a whole, or with the individual practitioner? Should all registered medical practitioners be free to take part in the work (the "panel system"), or should the service be staffed by selected practitioners only? Should advice and treatment be sought and given as far as possible on the lines of private practice, or should this be by means of specially established "clinics"?

In Great Britain the contract for service is made with each individual practitioner, though this, of course, does not in any way prevent the negotiations as to terms and conditions of service being conducted, on behalf of all practitioners concerned, by a central professional organization. In Japan, on the other hand, the agreement as to medical benefit under the insurance scheme is between the Government and the Japan Medical Practitioners' Association. It consists of thirty-five articles, and is signed by the president of the association and by the director of the Bureau of Social Affairs. Under this agreement the medical attendance on all insured persons is in the hands of the association (except where patients are placed in public hospitals), which has made itself responsible for providing, regulating, and supervising such attendance for the whole of the insured population. Such a contract as this necessitates the adoption of some methods of inspection and detailed control which would not be very congenial to those influenced by either British or Dutch professional traditions, and entails a responsibility for administrative detail which probably neither the British Medical Association nor the Medical Association of South Africa (British Medical Association) would readily undertake. Nevertheless, this arrangement is said to have worked well in Japan during the short period of two years during which it has been in operation, and to have proved so far satisfactory to the profession in that country. It is for the practitioners of South Africa to say whether it is attractive, or otherwise, to them.

#### SOME FUNDAMENTAL CONSIDERATIONS.

Two of the fundamental principles which the profession in Great Britain has found it essential to adopt and maintain in connexion with national health insurance are: (1) the right of every registered medical practitioner to take part in the service if he chooses to accept and abide by the prescribed conditions; (2) as complete a freedom of choice by insured person of doctor, and by doctor of patient, as circumstances allow.

It is held to be inequitable and unjust that when a Government makes communal provision for medical attendance on any considerable proportion of the population it should cut off so large a field of work from those who are legally qualified to practise therein and reserve it for the chosen few; and it is regarded as important to maintain the methods and traditions of established medical practice as far as possible, and to preserve that personal relationship between doctor and patient which is so valuable an aid to success in the treatment of disease and the maintenance of health. There is no reason why these principles should not apply to consultant and specialist practice as well as to that of the general practitioner, and they should hold good just as much in South Africa as in Great Britain. In South Africa, indeed, the setting-up of an insurance scheme would afford an opportunity of so applying these principles as to do away with certain undesirable features associated with the present system of selected "district surgeons" and medical officers of the railway service. There are, on the other hand, some possible administrative and financial advantages about a system of selected staffs; but it is not easy to suppose that the profession in South Africa will consider that these outweigh the considerations held to be so vital by the profession in Great Britain and elsewhere.

It is largely to preserve the desirable features of private and family practice, with its invaluable opportunities for the teaching of personal and domestic hygiene, that the medical profession in Great Britain has preferred the system of domiciliary and consulting-room work to that of the separately established central clinic as the ordinary method of giving medical attendance. The British Medical Association advocates these methods as being generally preferable even in consultant and specialist practice, though it is recognized that in certain areas and for particular purposes the establishment of such "centres" may be useful under suitable conditions.

The circumstances in South Africa differ from those in Great Britain, and make the determination of this question of the method of giving medical attendance under a health insurance scheme a matter of peculiar difficulty and importance. It might be easier in several respects (social as well as financial) to provide medical advice and treatment for Indians, Malays, natives, and coloured, perhaps for low-paid workers in general, at central clinics than in any other way. There are doctors in many towns who would desire to take part in a health insurance service, but who do not wish to cultivate practice among these classes of the population. Some of these doctors would, however, not object to giving sessional attendance at a clinic for such persons. This applies alike to general practitioners and to specialists.

It is highly undesirable that the profession should be divided into distinct classes, and that any excuse should be given for the statement that an inferior kind of medical attendance was provided for the native as compared with other insured persons. For this reason, among others, it may be found that some combination of clinic and domiciliary medical attendance may be judged suitable. In coming to a decision it is to be hoped that the Association in South Africa will in no case abandon without due cause the more customary and private methods of practice in connexion with insurance work, and that, if any limited system of clinics is established at all, the arrangements insisted upon will be such as to prevent the selection of a permanent staff of medical officers to do the clinic work to the exclusion of their fellows who may be similarly qualified. It is quite possible, even in clinics, to devise a system of sessional attendances which will spread the work as widely as possible over periods of time.

There is one further question as to method which the Medical Association of South Africa (British Medical Association) is asked to reply to: this is the method, as distinct from the amount, of remuneration. Shall it be by capitation, by case value, by items of attendance, by sessional fee, or even by salary? In this matter the experience and the full consideration of the point by the profession in Great Britain may be regarded as almost the determining factor. The opinion in Great Britain is practically unanimous. It is that ordinary medical attendance under an insurance scheme should be remunerated by capitation fees, and specialist attendance by fees per item of attendance. If, however, there is any attendance at central clinics this should be paid for by appropriate sessional fees. If after some time experience shows that particular kinds of attendance at individual clinics can be stabilized at a salary corresponding roughly to the sessional fees in the special instance, there would be no objection to the naming of a yearly salary for such attendance, provided this is open to revision.

#### THE TASK BEFORE THE SOUTH AFRICAN PROFESSION.

The Federal Council of the Medical Association of South Africa (British Medical Association) and the Branches of the Association throughout the Union are faced with a task of much difficulty, requiring both knowledge and judgement. It is unfortunate that the great majority of the members of the Association in that country have no knowledge whatever of the actual working of insurance practice. In so far as this weakness can be remedied by the experience of the members of the British Medical Association in Great Britain, this is freely at the disposal of those who have the main responsibility in South Africa. Already something has been done to make this available.

There is every reason to believe that with a united and

effective and alert Association in South Africa, and with an apparently sympathetic and reasonable Parliamentary Commission, there may be established in the Union of South Africa a scheme for affording medical advice and treatment of all kinds to employed persons unable to provide it adequately for themselves which shall be consistent with the interests of the medical profession and greatly to the advantage of individual and public health.

## SCHOLARSHIPS AND GRANTS IN AID OF SCIENTIFIC RESEARCH.

### Scholarships.

The Council of the British Medical Association is prepared to receive applications for Research Scholarships as follows: An Ernest Hart Memorial Scholarship, of the value of £200 per annum, and three Research Scholarships, each of the value of £150 per annum. These Scholarships are given to candidates whom the Science Committee of the Association recommends as qualified to undertake research in any subject (including State Medicine) relating to the causation, prevention, or treatment of disease. Each Scholarship is tenable for one year, commencing on October 1st, 1928. A Scholar may be reappointed for not more than two additional terms. A Scholar is not necessarily required to devote the whole of his or her time to the work of research, but may hold a junior appointment at a university, medical school, or hospital, provided the duties of such appointment do not interfere with his work as a Scholar.

### Grants.

The Council of the British Medical Association is also prepared to receive applications for Grants for the assistance of research into the causation, treatment, or prevention of disease. Preference will be given, other things being equal, to members of the medical profession and to applicants who propose as subjects of investigation problems directly related to practical medicine.

### Conditions of Award: Applications.

Applications for Scholarships and Grants must be made not later than Saturday, June 2nd, 1928, on the prescribed form, a copy of which will be supplied on application to the Medical Secretary of the Association, B.M.A. House, Tavistock Square, London, W.C.1.

Applicants are required to furnish the names of three referees who are competent to speak as to their capacity for the research contemplated, to whom reference may be made.

## ROYAL MEDICAL BENEVOLENT FUND.

At a recent meeting of the committee sixty-one cases were considered and £1,057 voted to fifty-one applicants. Since the beginning of this year a total of £2,203 has been made in grants to urgent cases of distress. The following are short notes on a few of the cases helped.

Widow, aged 39, of M.B.Aberd. The husband died of cancer in December, 1927. He was just emerging from financial difficulties, having recently started a new practice, when he became ill and died of cancer a year and a half later. The practice was sold for £500, all of which went to pay his debts and the expenses of the illness. The widow has been left with a boy, aged 14, and a capital of only £45. Voted £24. The case was referred to the Guild for work to be obtained for the widow.

Widow, aged 54, of M.D.Camb. The husband died of cancer in December, 1927. He was just emerging from financial difficulties, having recently started a new practice, when he became ill and died of cancer a year and a half later. The practice was sold for £500, all of which went to pay his debts and the expenses of the illness. The widow has been left with a boy, aged 14, and a capital of only £45. Voted £24. The case was referred to the Guild for work to be obtained for the widow.

Daughter, aged 53, of M.B.C.S.Eng. has since the death of her father supported herself and her delicate sister by literary work. In 1925 she became ill from overwork. She has gradually sold all she had, and now she and her sister are living in lodgings, for which they pay £1 a week, including food for both. Voted £26.

Daughter, aged 65, of L.R.C.P.Ed. was working as a governess in Russia at the time of the revolution. She was forced to leave, and lost all her savings. She has returned to this country at an age when it is impossible to continue work. Her total income is only £60 a year. The Fund voted a further £26.

The demands for help increase and subscriptions are very urgently needed, and should be sent to the Honorary Treasurer, Sir Charters Symonds, 11, Chandos Street, Cavendish Square, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

SATURDAY, APRIL 21ST, 1928.

## LONDON SEWAGE AND THE RIVER THAMES.

THE spending of a quarter of a million pounds on what is essentially a health measure is a matter of some moment, even in London, where big figures cease to arrest attention by reason of their familiarity; and when we learn that this expenditure is an instalment only in a proposal which may involve in its completion a scheme for dealing with a problem some twenty to fifty times the dimensions of that now attacked, the matter becomes of more than passing interest.

On February 23rd last the London County Council decided to embark on an outlay of £250,000 to install plant capable of dealing with quantities of sewage effluent of from five to ten million gallons a day. At the present time the volume of sewage effluent daily entering the Thames at Barking and Crossness, the Council's outfalls, is some 260 million gallons. "These streams form, in effect, tributaries of no inconsiderable size to the River Thames. Discharge from the outfalls is constant, and the effluents mix with the river and take part in its movement. A progressive passage of all the water in the river takes place in the direction of the sea, but, owing to the tide, such passage is not continuous in its direction. Owing to the oscillation of the tide, the progress of effluent seawards from the outfall is subject to reversal. A particle of effluent starting from one of the outfalls at the beginning of the ebb tide can only go a few miles down the river before it is met by the incoming flood tide. It is thereby carried back, although not back to the original point of departure. On the succeeding ebb it gets further down the river than before, only to be carried backwards by the next flood. The rate of curtailed progression continues until ultimately it reaches the sea. On the flood tide the movement of effluent in the first instance is up-river, and, in consequence, the condition of the river is affected throughout its course in its passage through London." What is the nature of this effluent affecting the condition of the river throughout its course in its passage through London? The sewage of London is subjected at the outfalls to sedimentation. "The precipitation operations at the outfalls result in the deposition of the cruder suspended matters in the sewage. The organic matters which have passed into solution flow out with the effluent and are the principal factors of pollution. The effluent also contains the lighter suspended matters which the disintegration of the grosser solids in the sewers has produced." The report from which we have quoted does not inform us of the extent to which these principal factors of pollution have affected the River Thames in its passage through London; but we are left to infer that a degree of pollution has been reached which it would be unsafe to permit to continue. "Experience has proved that the calls which are being made on the London main drainage system, and on the capacity of the river as the final place of disposal, have reached a point when further steps should be taken."

<sup>1</sup> Report of the Main Drainage Committee brought up to the London County Council on February 21st, 1928.

It is a tribute to the sagacity of the members of the London County Council that they have not waited until the evidence of the senses has forced a public recognition of conditions which could not be tolerated. And while, on the other hand, the Council has not moved precipitately, it appears not to have wasted the period of grace allowed it for deliberation. In addition to sustained consultation with its own past and present officers, visits of inspection to provincial authorities engaged in grappling with kindred but even more pressing problems, and the authorization of prolonged and practical scientific investigations, the Council has from time to time consulted the most eminent experts it could find to advise it in the stupendous undertakings which in the long run would obviously have to be faced. It is clear, from the different solutions of these problems that have been propounded, that the gain in knowledge has enormously contracted the scope of the Council's commitments, as it has simplified difficulties and economized resources. In 1890 it was foreseen that what is now recognized as the immediate duty of improving the methods of London sewage disposal would ultimately have to be discharged, but at that time it was regarded mainly as an engineering problem involving works far more costly than any which are contemplated to-day. Two eminent engineers, Sir Benjamin Baker and Sir Alexander Binnie, who had been consulted, reported in February, 1891. The course of action advocated by them, if and when the quantity and quality of effluent passing into the river became more than could be assimilated by the river without causing nuisance, was to move an outfall further down the river. Shell Haven was suggested as a possible site, and the engineers also expressed the opinion that if it were considered imperative to discharge the metropolitan sewage into the sea in its crude condition without any risk of injury to the estuaries of the Thames, the Blackwater, and the Crouch, then a project for an outfall sewer fifty-six miles long, from Crossness to the deep water of the ... would be found worthy of serious ... to the advance in knowledge of sewage purification, it is now seen that such colossal expenditure as would be involved in engineering undertakings of this magnitude is not only unnecessary, but would provide no real remedy. Whether discharged into the sea or into the estuary, sewage in such volume as that of London would necessarily have to be treated. Fortunately, after prolonged study of the ways of natural purification, methods of treatment have been evolved which entail no sacrifice of the costly plant already provided, and are applicable at the sites of the present outfalls.

The County Council has satisfied itself that what is known as the activated sludge method is applicable to the treatment of the effluent from the area it administers. Exhaustive investigation has shown that this effluent pollutes the Thames in course of its passage through London to a degree at which further steps for its improvement are imperative. The method which, after the fullest investigation, the Council has decided to apply provisionally, on a scale which can be regarded only as an instalment, involves no scrapping of the present inadequate methods of sewage treatment. It begins where the present treatment leaves off, and carries purification to an innocuous stage at which, without menace to the great health interests of the metropolis, the effluent may safely be discharged into the waters of the Thames. It is hoped that, as a result of the experience gained in proceeding by degrees instead of by a single comprehensive scheme, economies will be effected and, in respect of

operations on so vast a scale, the errors of inexperience avoided. Large as are the sums of money involved, the cost of treating London sewage is relatively low.

To London, clustered on the banks of the Thames, the preservation of the salubrity of the river is of the first importance. Since only the tidal waters are affected by the large volumes of effluent they receive, the problem of purification is a comparatively simple one—much simpler than that of the riparian authorities of the upper reaches, where effluents mingle with the potable waters which supply London. But although simple it is of first-rate importance. Nothing can be permitted which threatens the healthiness of the metropolis and its environs. The great waterway and spacious and unobstructed airway of the Thames estuary is doubtless one of the main environmental factors which have given London the enviable position in regard to health of which it is so justly proud; and the London County Council is to be congratulated on its watchfulness and prescience, its courage and faithful discharge of primary obligations, in the great enterprise on which it has so unostentatiously embarked.

### THE NATIONAL HEALTH INSURANCE BILL.

The National Health Insurance Bill was given a second reading by the House of Commons just before the Easter recess. This bill proposes to make changes in administration and in connexion with additional treatment benefits, the proposals being mainly based upon the less important recommendations of the Majority Report of the Royal Commission on Health Insurance. A summary of the provisions of the bill was given in our *Supplement* of March 17th last (p. 89), and a full report of the debate on the second reading will be found in the *Parliamentary Notes* in last week's *Journal* (p. 645). It is by no means easy to understand from the text of the bill itself the effect of its provisions; but a careful consideration of that text, of the official explanatory memorandum, of the debate on the second reading, supplemented by the notes of an interview between representatives of the Insurance Acts Committee and of the Ministry of Health, suggests that there is a real danger of our profession treating the matter too complaisantly. During the preparation of the bill, and, indeed, since its introduction, the Ministry of Health has stated that there is but little in the bill that affects the medical profession. It is true that with most of its clauses the profession is not directly or seriously concerned, but it may be found that certain sections of the bill raise once more questions of fundamental importance to the medical profession, and that there will be grave danger if some of these sections pass unamended.

With many of the provisions of the bill there will be hearty agreement. The considerable simplification with regard to contributions, arrears, and benefits effected by Clause 1 (and some others) should help towards a smoother working of a system, all parts of which have suffered from over-elaboration and lack of uniformity. The stoppage of the subterfuge by which new institutions, not otherwise qualified for recognition, have been brought into existence in South Wales through a misuse of the power of making "collective own arrangements," will be welcomed. The establishment of real insurance conditions for deposit contributors who are unable through ill health to join any approved society will remedy an obvious hardship. An increased control by the Ministry over the rules and maladministration of approved societies should tend to lessen gross abuse and injustice. The

establishment of two new classes of insured persons will not be objected to, since they are of the same type as those technically employed under a contract of service, though the extension of the insurance scheme to some 25,000 additional persons is not without its interest to medical practitioners.

It is those parts of the bill directly or indirectly affecting the provision and administration of additional treatment benefits which require the closest scrutiny, and which may be found to necessitate either important amendment or strong opposition. These are Clauses 4 and 14, the first schedule, and parts of the second and third schedules. It will be remembered that the most important and urgent of the recommendations of the Royal Commission was that the scope of medical benefit should be extended so as to include for all insured persons consultant and specialist services. The cost of such extension was estimated at about £1,250,000 a year, and was to be provided by a very limited pooling of future surpluses of approved societies. In the course of the debate on the second reading of the bill it was reiterated by several members of the Opposition that the absence of provision for a general specialist service was due to the effect of the Economy Act of 1926. There can be no sympathy with this statement in the minds of those who remember, or refresh their memory with regard to, the provisions of that measure and the debates thereon (see articles in the *British Medical Journal* of April 10th and 24th, 1926, pp. 663 and 750). Sir Kingsley Wood was correct when he said that "the fact that there had been no provision made in the bill for specialist services had nothing to do with the Economy Act. But for the opposition of the approved societies it would be perfectly possible to put into operation the scheme for specialist services without bringing any additional funds into the national insurance system at all." It is owing entirely to the shortsightedness and selfishness of the larger and more prosperous approved societies that such a scheme is not now in operation, or at least under discussion. In its absence the Ministry of Health naturally desires to make the most of whatever additional treatment benefits are possible for a certain number of insured persons. Such a patchwork system, however, can never be satisfactory either to the patient or to the medical profession or to the Ministry, and the conditions governing it require the closest scrutiny lest they should be contrary to the interests of the profession and prejudicial to the future development of national health services.

The proposals of the bill in this connexion may be described as follows: (1) to abolish, as an additional benefit "medical treatment and attendance for any person dependent upon the labour of a member"; (2) to add as a new additional benefit "payments to approved charitable institutions in respect of any treatment of members required for the prevention or cure of disease, not being treatment within the scope of any other additional benefit or of medical benefit"; (3) to restate somewhat more accurately the remaining additional benefits; (4) to give power to the Minister of Health to make regulations "with respect to the administration of any additional benefit and with respect to the arrangements for the provision of any service towards the cost of which payment may be made by way of additional benefit"; (5) to define more clearly the nature of a "charitable institution" to which an approved society may make contributions; (6) to repeal the present requirement that additional benefits "which are in the nature of medical benefit" shall be administered by and through Insurance

Committees, and not by approved societies. The full effect of these amendments can be appreciated only if they are read together.

Requirements which it is essential for the profession to safeguard or secure are: (1) that there shall be no possibility of any approved society seeking to provide, administer, or control any medical service either directly or "by resorting to devices which are not conducive to good administration" (to quote the Ministry); (2) that there shall be no compulsory negotiating with any approved society or representatives of approved societies as to the terms and conditions on which medical advice and treatment will be given; (3) that there shall be free choice of specialist or consultant, and (to quote a phrase used by the Minister of Health, Mr. Chamberlain, during the second reading debate) that "no one must be compelled to go to a clinic if he would rather go to a private practitioner"; (4) that there shall be a suitable guarantee that a general specialist service shall be established as soon as possible, and that meanwhile any additional treatment benefit that becomes widespread shall be made statutory for all insured persons, and that in either case the service shall be administered by Insurance Committees or public bodies corresponding thereto, and not by approved societies.

It is clear that some of these requirements are not met by the bill as it stands. One or two phrases used by the Minister of Health in his speech on the second reading seem to make it doubtful whether he realizes exactly what the medical profession wishes or the importance it attaches thereto. The profession can never give away in the case of the consultant or specialist what it has secured for the general practitioner; and it is bound to have in mind the situation in which it would be placed if a Minister of Health entirely sympathetic to the wishes and ambitions of approved societies were to make regulations and to interpret Acts of Parliament. Both Mr. Chamberlain and Sir Kingsley Wood gave the undertaking that amendments put forward with the object of improving the bill would receive most careful and sympathetic consideration from the Government. With this in mind, no doubt the Insurance Acts Committee and other committees of the British Medical Association concerned will be able to obtain such explanations, assurances, and amendments as shall secure the aims of the profession.

#### THE WELFARE OF HOP-PICKERS.

DURING recent years the public has become increasingly interested in the welfare of those thousands of town dwellers who annually migrate, mainly from London and from the Black Country towns, to the hop fields of Kent, Worcestershire, and Herefordshire. These folk, who are mostly in humble circumstances, combine business with pleasure, and have for many years—even generations—regarded the picking of hops as a means of affording themselves, their children, and other people's children a three weeks' holiday in the country. Of the 25,597 acres of hop gardens in this country, 15,686 acres are situated in Kent, and into these spacious gardens of the Weald there debouch annually from the congested quarters of East London some 70,000 pickers, mainly women and children. No one will deny that the conditions under which these thousands of casual workers undertake their journeys to and from the hop fields have improved enormously during the past five years; those with a long experience of pickers' camps will further agree that, generally speaking, the conditions of camp life have reached a higher standard than existed before the war; and there is

agreement amongst local observers that the conduct of the hop-pickers and the general health of their children have altered considerably for the better during the last twenty years. There are visible signs, moreover, that the medical necessities of the hop-pickers are receiving more and more attention as each season comes round. But from a paper on the health of hop-pickers and the sanitation of hop-pickers' encampments, read by Dr. Alfred Greenwood, county medical officer for Kent, at a sessional meeting of the Royal Sanitary Institute held in Maidstone on April 13th, and from the discussion which followed the paper, we learn that, in the opinion of the county health authorities, there is need for still further improvement, both as regards the sanitation of camps and in the organization of medical services. Dr. Greenwood acknowledges that some camps are satisfactory in every way, and indeed we know of some Kentish hop-growers who have gone considerably further than the letter of the by-laws, and whose arrangements for their temporary employees are beyond all praise. In the majority of camps the present-day conditions are not essentially unsatisfactory, and they are improving; but the word "disgraceful" is not too strong to describe the insanitary conditions which have often been observed in certain other camps. Gross overcrowding, unsatisfactory and dangerous water supplies, and the neglect to make and maintain proper conservancy arrangements in hop-picking camps are grave defects which it is the duty of local authorities to prevent, not only in the interests of the hop-pickers, but in the public health interests also of the local inhabitants. We gather, however, that Dr. Greenwood is not satisfied that all the local authorities concerned make sufficient use of the machinery at hand for dealing with these matters, and he considers that some councils have in certain instances shown unmerited leniency when administering the existing by-laws. He suggests that the registration of encampments and the granting or withholding of annual licences would improve matters. From the point of view of public health administration this step probably would be helpful, provided registration were made applicable to all existing camps, and not merely to those that might be started in the future; and provided also that the local authorities—who would administer the licences—were not unduly lenient. What the economic and political results of compulsory registration upon the hop-growing industry would be is another question. In the meantime, we think it quite possible that more might be done to gain the support of the local branches of the National Farmers' Union, which can probably bring useful pressure to bear upon recalcitrant and backward farmers. The question of how best to co-ordinate the various voluntary medical organizations already in the hop gardens, and the encouragement of others where wanted, is certainly one ripe for consideration, and we have no doubt that the Ministry of Health would consider sympathetically any wish which local authorities might express regarding the formation of a joint committee to discuss the matter.

#### THE THERMO-CAUTERY FOR SEPTIC LESIONS.

THE thermo-cautery has been used in the treatment of a variety of lesions for many centuries. Hippocrates refers to a case of abdominal suppuration in which the discharge of pus ceased after cauterization, and Abulcasis, who died in 1013, and who wrote a summary of Islamic surgery which was regarded as a classic in the mediaeval schools of Europe, mentions more than forty uses of the cautery. Early in the nineteenth century "moxae," consisting of rods of specially prepared charcoal, which were ignited and then applied to the skin, were used in Paris and elsewhere as counter-irritants in the treatment of chronic abscesses, and even in chronic inflammations of the respiratory organs. Recently Professor Bier of Berlin has reintroduced the

use of the cautery into the treatment of suppurating lesions, and reports<sup>1</sup> the results obtained in 402 cases, a large proportion of which were very satisfactory. In all the cases treated since 1925 he has used a thermo-cautery designed by Hadenfeldt, which is heated by a mixture of air and benzoline under pressure inside a cautery point of aluminium bronze, as he has found this much more effective than other types. The technique employed in the treatment of large abscesses, including abscesses following trauma or abdominal operations, is as follows; minor lesions are not included in this series. The abscess is freely opened, as much necrotic tissue as possible is removed, and the whole is scraped with sharp spoons. The cavity is then cleansed of blood, pus, and detached granulation tissue, and is cauterized. It is desirable to have the cavity as free from blood as possible, either by working in a bloodless field or by carefully tying bleeding vessels. The wound is then closed without drainage, catgut sutures being used where necessary for deep structures, while for the skin edges a "corselet" dressing is employed; this is described by F. Bunge<sup>2</sup> as consisting of a strip of gauze attached to the skin on either side of the wound by some form of glue, preferably mastisol. The two edges of the wound are then brought into apposition and kept there by lacing a silk thread across and across over small dress hooks, previously sewn to the two strips of gauze. The immediate local result of cauterization is as a rule an acute reactionary inflammation with abundance of pus, often foul smelling; in spite of this, however, the pain is relieved, and much better scars, sometimes even linear in type, are obtained by this method than when drainage is employed. A brisk general reaction, with rise of temperature and sweating, is common. The method has also been adopted with good results in the treatment of suppurating joints, in several knee cases described the inner surface of the capsule was scraped and cauterized, care being taken to avoid the cartilage, and the wound then closed. In the treatment of necrosis of bone following trauma or osteomyelitis the results of cauterization have been no better than those obtained by other operative measures; for chronic bone abscesses, on the other hand, Bier considers this method superior. In suppurating tenosynovitis the inner surface of the tendon sheath has been cauterized, but how the results in these cases compare with those of other methods is still uncertain. Bier ascribes his results to the inflammatory reaction produced by the cautery, and considers that the effects attributed to the specific virtues of various fluids used to irrigate suppurating wounds are really due to an analogous inflammatory reaction induced by their irritant properties. Superficial scarification of the skin with the cautery as a counter-irritant he does not consider of much value. He gives, however, a preliminary account of a number of cases of generalized septic infection and pyæmia in which the focus of sepsis was more or less inaccessible, and which were therefore treated by cauterization at the "situs of election." For this purpose he reflected an area of skin and subcutaneous tissue the size of the palm of the hand or larger, generally near the costal margin, carefully applied the cautery to its deep surface and to the exposed surface of the subjacent musculature, and then sutured the wound again. As a result certain tissue constituents are disintegrated, and the beneficial effects recorded in a small proportion of these cases are thought to be due to the absorption of these disintegration products and the consequent general reaction, evidenced by the associated pyrexia and accelerated pulse rate. How this differs from the reaction produced by the various specific and non-specific agents recommended in recent years for a similar purpose is not stated. Since in nearly all the cases included in the last group the prognosis was

practically hopeless before the treatment was applied, it is not surprising that the mortality rate is high. Summarizing his conclusions, Professor Bier states that many details of technique still require elaboration before this method can be used with safety and to the best advantage in the treatment of the severer generalized forms of sepsis.

#### THE NATIONAL PHYSICAL LABORATORY.

THE report for 1927 of the National Physical Laboratory,<sup>1</sup> although it runs to 250 quarto pages, is the bare minutes of the many-sided work carried on at Teddington. The special investigations undertaken at the laboratory are generally of a kind which extend over a period of years, "creeping on from point to point," and even when they are completed, or a stage in them is completed, it is not into the annual report that the work goes, but in papers communicated to appropriate bodies. During 1926 and 1927 the number of official communications made by the staff of the laboratory to scientific societies or technical journals was 165, and besides these a large number of papers were contributed unofficially. The annual reports merely give a bird's-eye view of an almost bewildering activity carried on in six principal departments—namely, those of physics, electricity, metrology, engineering, aerodynamics, and metallurgy and metallurgical chemistry. The physics department alone has a staff of just upon a hundred. Much of the work done at the laboratory is routine testing. For example, half a million clinical thermometers were tested there last year; also 10,000 lenses and other optical instruments. Weights, balances, measures, chronometers, all kinds of instruments of precision, are verified. Again, the laboratory furnishes a standard for radiological apparatus; 41 radium preparations were examined during the year, including a few radium waters and the like, tested by the alpha-ray method. The samples of protective materials tested numbered only 19, as compared with more than 200 a couple of years ago, and 17 x-ray installations, including these of several of the principal London hospitals, were examined by the staff of the laboratory. A great deal of radiological work is proceeding, but it is directed at present mostly to the use of x-rays in the industrial sphere. Work is being done, however, on the measurement of x-ray intensity and dosage, for which a special ionization chamber, where the ionization is produced in a gas at high pressure, has been set up. High-voltage research is actively proceeding. Million-volt transformers are being or have been installed in a special high-voltage building, and we know that in various electrical institutions, including those concerned with radiology, very much is hoped from these experiments in high voltage. Illumination research is another matter to which the laboratory is paying attention. A comprehensive investigation is taking place into the effect of glare on visual acuity, the value of different systems of illumination for the carrying out of fine work, and a proper diffusing glass for street lighting. The acoustics of buildings is another field of operation. Very few public halls can be said to be perfect acoustically, but in this respect audiences suffer long and are kind. It is possible to remedy a good deal of the trouble in a defective building by ceiling canopies or linings and by the use on appropriate occasions of electrical amplifiers with loud-speaking projectors (as is done in the Great Hall of the British Medical Association House), but the elimination of the defect in many buildings can only be accomplished by structural alteration, which goes to prove the need for consulting an acoustical expert before a building is erected. Another piece of work carried out at the laboratory is the investigation of dental amalgams, both in regard to the

<sup>1</sup> *Medizinische Klinik*, February 16th, 1928, p. 201; February 17th, p. 245.

<sup>2</sup> *Ibid.*, p. 211.

<sup>1</sup> Published by H.M. Stationery Office, 7s. 6d. net.

structure of the alloys and the behaviour of the actual amalgams as used in dental practice. It has been suggested in Germany that there is a serious risk of mercury poisoning arising from the presence of amalgams in the mouth as dental fillings, and this is being checked at the laboratory by determining the loss of mercury by volatilization when a stream of air at the temperature of the mouth is aspirated over dental fillings. The tests are being made on teeth in which amalgam fillings have been inserted in the dental department of Guy's Hospital. Another piece of work is being carried out for the Food Investigation Board. This includes the devising of an instrument for recording the deposition of dew on fruit in cold storage. Another apparatus is a "spear" thermometer of the distant reading type for use in the investigation of temperatures in chilled meat transport, and yet another an oxygen analysis apparatus suitable for use in connexion with the gas storage of fruit. This brief review glances only at a few out of a thousand things that engage the ingenious brains at Teddington. The work done there covers the whole range of applied science, including, for example, wireless transmission, the theory and practice of flying, the methods of testing magnetic material, the measurement of colour, and innumerable other matters, all of which, some more directly and immediately than others, benefit the life of the community.

#### STERILIZATION OF THE FEEBLE-MINDED IN ALBERTA.

It is stated, on the authority of the Ottawa correspondent of the *Times*, that the Legislature of the Province of Alberta has passed the Sexual Sterilization Bill, which now awaits the assent of the Lieutenant-Governor. The Government is said to be assured on high legal authority that the bill is constitutionally sound, and, this being so, assent may be presumed; nevertheless, the Opposition threaten to test the validity of the measure in the courts. This is an interesting issue; but in any event it requires very little scientific knowledge or acumen to prophesy confidently that the results of the passage of the Act and its enforcement will be socially futile, if not harmful. It may, indeed, be doubted whether, in spite of the declaration of the Government, the Act will ever be really enforced; probably it will soon fall into desuetude, as in almost all those American States where similar legislation remains on the Statute Book. Scarcely any fact is more securely established than that it is only a small, almost negligible, minority of mentally defective persons who are the offspring of parents themselves certifiably mentally defective; so that the prevention of parenthood in the case of all such persons would have no marked effect upon the number of mentally defective children in the next generation. Under the Alberta bill it is only a limited number of mental defectives who could be dealt with in this way in any case. They are defectives who, being confined in mental hospitals, could, in the unanimous opinion of a board composed of two medical practitioners and two laymen, all specially appointed, be safely discharged if the danger of procreation were eliminated. Even if such a unanimous opinion were forthcoming, the patient may not be operated upon without his own consent, if he is capable of giving it, or, if incapable, without the consent of the husband, wife, parent, or guardian, as the case may be. Thus even if a number of these unfortunate persons should be induced to agree to sterilization as the price of their freedom—a choice with which it is cruel to confront them—it is clear that only a minority of a minority of the feeble-minded population will ever be subjected to the necessary surgical procedure. The Government contended that complete segregation was even more cruel. This is, of course, far from the truth, provided that a proper selection of cases for segregation is made and that the conditions of the institution or colony

in which they are placed are what they should be. It is now well established that a considerable proportion of mentally defective persons are not in fact socially defective, and may safely be left in the general community with only a small amount of supervision; and it is found that those who are mentally and socially defective to a degree requiring segregation are, as a rule, happier in their safeguarded surroundings than in a community to which they feel themselves unsuited. The Alberta experiment, if carried out, will be watched with interest, but experience has already proved that it is unnecessary and mistaken.

#### EXERCISE AS A THERAPEUTIC AGENT.

It is only a few weeks since we remarked on the increasing interest taken in Germany in the medical aspect of various sports and exercises.<sup>1</sup> Now from France there comes a warning, by Dr. Maurice Boigey,<sup>2</sup> against the haphazard prescribing of exercises for therapeutic purposes without due regard to the age and condition of the subject. He records three cases of death following such indiscriminate exercises. The first was a man, aged 57, plethoric and suffering from hypertension, who died suddenly after performing a series of movements while lying on his back. Much cyanosis was present, and necropsy revealed intense congestion of the great vessels at the base of the brain and a haemorrhage in the left third ventricle. Another man, 49 years old, slender and apparently healthy, was, however, suffering from compensated syphilitic aortic insufficiency; this being overlooked, he was advised to run quietly a few hundred metres every morning. During one of these runs he experienced a sudden feeling of suffocation, and died on reaching his home, after complaining of agonizing pain in the retrosternal and precordial regions. The third patient, a rather plethoric and hypertonic man of 59, was recommended to change his daily cold bath for a tepid one. Contrary to this advice, in the autumn he began sea bathing, and during the third bath he was attacked by sudden intense headache; he reached home with difficulty, and next day had all the symptoms of a right hemiplegia. It is well known that the vascular constriction caused by cold water at the moment of immersion produces a brief phase of hypertension, and that this is especially dangerous in persons nearing 60 who already have hypertension. In this connexion we may recall a note printed in our issue of August 28th, 1926 (p. 393), referring to Dr. Baudouin's elaborate instructions for sea bathers. Dr. Boigey agrees that exercise is a valuable therapeutic agent, but contends that the kind and the amount need judicious regulation. For sedentary, hypertonic, and plethoric individuals, those past the age of 50, and the subjects of latent or compensated heart disease, this form of treatment, he says, may be beneficial, but the movements should be carried out with the head in an upright position to avoid cerebral congestion, and they should not be too vigorous. It appears, then, that a little common sense—a quality in which the practitioners of our own country are not usually lacking—is as much needed in prescribing "physical jerks" as in other branches of therapeutics.

#### THE HOSPITAL PROBLEM IN VICTORIA.

THE hospital "problem," it appears, is causing no less concern in Australia than in this country, and the Victorian Government, in its search for enlightenment, some time ago delegated Professor R. J. A. Berry, dean of the Faculty of Medicine in the University of Melbourne, to undertake on its behalf a tour of investigation abroad. Professor Berry has now returned to Australia after visiting some 150 centres of medical education and treatment in Great Britain, Canada, and the United States, and

<sup>1</sup> *British Medical Journal*, March 3rd, 1928, p. 365.

<sup>2</sup> *Bulletin de l'Académie de Médecine*, February 21st, 1928.

has put forward a scheme for the creation of a great medical centre for Melbourne to co-ordinate and extend existing agencies. Addressing a recent meeting in that city, Professor Berry said the trend of affairs in hospitals, as in other departments of life, was towards the establishment of more complete and effective units. Modern progress made it a requirement that there should be a group of schools, hospitals, and institutes, all dovetailed into a general plan of education. In such centres all the knowledge now available to medical science could be brought to bear upon the treatment of disease and for the purpose of educating practitioners. They were not designed merely to serve a local need; the benefit of a medical discovery in Melbourne at once accrued even to people in Siberia, as well as to people in London and New York. For the creation of a Victorian health centre in Melbourne they required: (1) a university school of medical, dental, and allied sciences; (2) a university clinical hospital of 200 or 300 beds, which should be retained for post-graduate work and paying patients; (3) a general hospital of 500, 600, or 700 beds; (4) medical co-operation and the closest university association between these and all other metropolitan and leading provincial hospitals; and (5) one central guiding administration and administrator. Professor Berry said that everywhere, especially in Canada and the United States, he found medical schools and hospitals being removed from one site to another to give effect to centralization schemes. The advent of scientific medicine had given longer life to the present generation, and the medical centre movement, which was rapidly developing all over the civilized world, promised to give still longer life to the generations to come. It promoted the supply of more efficient doctors, nurses, and health workers, with a greater certainty of providing relief in disease. The extent to which conditions in Australia resemble those of this country are revealed in some of Professor Berry's remarks regarding the present position in Melbourne. He is anxious, like so many in this country, to see immediate provision made for the expansion of hospital accommodation; but, while a keen advocate of centralization, he thinks that the identity and autonomy of the existing hospitals should be preserved.

#### THE EVOLUTION OF A HEALTH DEPARTMENT.

THE Public Health Department of the State of Illinois, on the occasion of its jubilee last year, published a record<sup>1</sup> of the health of the State from the time of the first settlers to the present day. Little is known of the health conditions of the early Indian inhabitants. The first white settlers, French-Canadians, arrived in 1670. Their writings contain few references to health; they may be presumed to have been a healthy race. The British, who occupied the territory from 1763 to 1780, suffered severely from malaria and small-pox. In 1780, when the British fort was captured, American colonists began to settle in the State. As their numbers increased disease became prevalent and assumed menacing proportions. Malaria was the principal illness; it affected every member of the community, young and old alike. Typhoid fever, though present, was obscured by the dominating malaria. The cholera pandemics of the nineteenth century reached Illinois on more than one occasion, and small-pox was common. Since the establishment of the State Department of Public Health in 1877 malaria has almost disappeared, mainly as a result of the drainage of swamps. Typhoid, which rose as malaria fell, has yielded in its turn to improved sanitation, and small-pox, despite resistance to vaccination, has been brought under control. Hospitals and laboratory facilities have

been provided, and an efficient child welfare service has reduced the heavy mortality among infants and young children. The unavoidably incomplete vital statistics of the early years of the department's work render accurate comparisons difficult, but it may be noted that the average age at death has risen from 33 in the days of the settlers to 58 at the present time. Admitting that diminished activity on the part of the Indians may have concurred in some measure to this result, the fact remains that genuine health progress has been made, and the department, in the closing words of its report, may face the future with confidence.

#### DAYLIGHT IN BUILDINGS.

ONE of the most important problems of city life is the arrangement for lighting of the interior of buildings. There has been great improvement in artificial lighting of recent years, but the problem of daytime illumination is as yet unsolved. The value of space tends to crowding of building, and this causes obstruction to lighting, however large and well planned the windows may be. Worse still are the effects of increasing height of buildings: houses that were formerly well-lighted are now overshadowed and their interiors are gloomy. The Department of Scientific and Industrial Research has turned its attention to this problem. In a paper on *Penetration of Daylight and Sunlight into Buildings* (London: H.M. Stationery Office, price 1s.) the present state of our knowledge is set out, and there is a promise of speedy inquiry into the hitherto uninvestigated questions that arise thereon. The lighting of a room is good or bad in proportion to the unobstructed sky area visible at the working or floor area. Where little or no sky is visible, as in a room on the ground floor of a well area, then the lighting is bad. Where a full sky is seen, as from a top floor room of an unobstructed house, the lighting is good. These conditions can be measured. The outside daylight on an average dull day is taken at 250 foot-candles, and it is found that the minimum interior lighting—the "grumble point" (that is, the point at which reasonable people will complain of poor light)—is 1 foot-candle. That means that all positions in the room which have a "sill-ratio" of less than 0.4 per cent. will be unsatisfactory. The chart of the area of a room which has visible sky can be plotted out and the ratio ascertained. Among other matters consideration is given to the effect of whitening the obstructing walls. This device is found to be of advantage so long as the whiteness is fresh, but in a city of smoke and grime the benefit is short-lived.

THE spring meeting of the British Orthopaedic Association will be held in Paris on Friday and Saturday, April 27th and 28th.

WE regret to announce that Mr. John Stephen McArdle, professor of surgery at University College, Dublin, and senior surgeon to St. Vincent's Hospital, died at the age of 69 on April 14th, after a long illness.

PROFESSOR G. ELLIOT SMITH, M.D., F.R.S., will deliver the Huxley Memorial Lecture at the Royal College of Science, South Kensington, on Friday, May 4th. The title of his lecture is "Conversion in Science."

THE formation of a Masonic Lodge in connexion with the British Medical Association is now being considered by a small committee. All Masons who may be interested are invited to apply for information to Dr. Hubert C. Bristowe, The Cottage, Wrington, near Bristol.

<sup>1</sup> *The Rise and Fall of Disease in Illinois*. By Isaac D. Rawlings, M.S., M.D., in collaboration with William A. Evans, M.D., D.P.H., Gottfried Koehler, M.D., and Baxter K. Richardson, A.B. In two parts. Illinois: State Department of Health, 1927. (Sup. roy. 8vo, pp. 432; illustrated.)

# NINETY-SIXTH ANNUAL MEETING of the British Medical Association, CARDIFF, 1928.

TOWER OF CARDIFF  
CITY HALL.

AFTER an interval of forty-three years the British Medical Association will hold its Annual Meeting in Cardiff this summer under the presidency of Sir Ewen Maclean, M.D., F.R.C.P., Professor of Obstetrics and Gynaecology in the Welsh National School of Medicine, who will deliver his address to the Association on the evening of Tuesday, July 24th. The sectional meetings for scientific and clinical work will be held, as usual, on the three following days, the morning sessions being given up to discussions and the reading of papers, and the afternoons to demonstrations. The Annual Representative Meeting, for the transaction of medico-political business, will begin on the previous Friday, July 20th. The names of the officers of the eighteen Scientific Sections were published in the *Supplement* of March 3rd, together with an outline of the provisional programme; further details will be announced from time to time as the arrangements for the work of the Annual Meeting take final shape. On the last day of the meeting (Saturday, July 28th) there will be excursions to places of interest in the neighbourhood. We publish below the third of a series of historical and descriptive articles on the city and its medical institutions, written for the occasion by Dr. Donald Paterson. The first appeared on December 3rd, 1927, and the second on January 28th, 1928.

## THE MEDICAL INSTITUTIONS OF CARDIFF.

THE earliest hospital in Cardiff of which record has been preserved was the Hospital of St. Mary Magdalen. Its dedication suggests that it was in origin a leper house or leper hospital, probably established in the fourteenth century, or perhaps earlier, to cope with leprosy then prevalent. By the year 1400 the institution, which had been founded and governed by the burgesses and commonalty of the town of Cardiff, with twenty-four beds "for leprous, poor, and feeble folk," had long been ruinous and derelict. Its lands, the "Manor of the Spital," as it appears in records, had fallen in value, and the decline of leprosy having deprived it of its appeal for the alms of the charitable, it vanished entirely. It is worthy of note that on the same site, at the commencement of Newport Road, more than four centuries later the first infirmary building, which became later part of the medical school, was erected.

### ROYAL INFIRMARY.

The rapid growth of the town made the problem of hospital treatment in the early part of the nineteenth century a very pressing one. The infirmary was founded in 1837, and though it has several times changed its name, like a street in a French town, it has remained true to the policy of embracing within its own walls, as far as possible, the various activities of hospital treatment demanded by the advance of medicine. With the exception of the hospital for seamen at the docks, the medical work of the town has centred, until recent years, in this institution. The original building—which was erected for

£3,550 at the sole expense of Mr. Daniel Jones of Beaupré, a solicitor of Cardiff, whose benefactions exceeded the sum of £10,000—provided for the accommodation of ten male and ten female patients. It was not without its early difficulties, for in five years we find the committee complaining of "damp walls, smoky chimneys, dry-rot in the skirting boards, imperfect pipes, and inadequate drainage." In 1866 it was enlarged by the addition of wings.

The infirmary was transferred in 1883 to a new building arranged on the pavilion system on the present site, regarded at the time as ample for years to come, but which before long proved to be insufficient. Necessary extensions soon covered the remainder of the site, and this had to be supplemented by adding a further story to the existing buildings. In spite of the difficulties imposed by a somewhat crowded site the demands of the ever-increasing work have always been met, and it is now one of the best-equipped hospitals in the country, with a record of excellent work. A new central

*Infirmary, Cardiff, Glamorganshire.*

out-patient hall, with suites of rooms for the various departments, was opened in 1908 by the late Sir William Osler, and, during the war additional buildings, at a cost of £35,000, were in course of erection. Provision has since been made for maternity work; to the extent of thirty-one beds and twenty-five cots, by the conversion of several houses on the opposite side of the road. The casualty department has been much enlarged, and the completion of the medical school and the introduction of clinical teaching made

THE ROYAL INFIRMARY, CARDIFF.

rearrangement imperative. The fine medical laboratory provided by the Rockefeller Foundation trustees is the latest acquisition. The main hospital now contains 380 beds, and considerable relief is afforded by a convalescent home of fifty-four beds, four miles outside the city.

Its nursing school has established a well-earned reputation. Instruction is highly organized, and its preliminary training school in Anthony House has long been a notable feature.

#### ROYAL HAMADRYAD SEAMEN'S HOSPITAL.

The rise of Cardiff as a port soon made necessary the provision of hospital accommodation for the seamen of many nationalities frequenting it. Accordingly the old 21-ton frigate H.M.S. *Hamadryad* was lent by the Admiralty at the time wooden hulls were being discarded. It was fitted up as a hospital with sixty beds, and opened in 1866, its main financial support being derived from a voluntary levy of 2s. per 100 tons register on all ships using the port. Moored in a creek or pill, and afloat during high spring tides, it served its purpose for forty years, and, in spite of being unsuitable in many ways, did excellent and successful work. Low ceilings made the wards difficult to ventilate, and in the operation theatre, lit by gas, the proceedings were liable to be interrupted by phosgene gas formed by decomposition of the chloroform vapour in the flame. This phenomenon was first described in this country in a paper based on observations made on board the old ship.

When the year of the Diamond Jubilee came it was decided to celebrate it by raising a fund to erect a permanent hospital. Besides giving a site the late Marquess of Bute, who took a personal interest in the proposal, made provision for its completion and equipment, and it was opened in 1907. The site, though suitable as regards position—it was washed by the tide, reminding the patient of his native element—was otherwise a difficult one to deal with. To provide foundations piers of concrete had to be carried down through nineteen feet of soft clay to the hard gravel—a very costly proceeding, which entailed placing the wards one over the other on three floors. It has three main wards of sixteen beds, each with a two-bed ward adjoining. The medical superintendent's house is separate from the hospital, but connected with it by a covered corridor. The building and equipment cost £30,000.

#### CITY MENTAL HOSPITAL.

This institution, of which the city is justly proud, has been a pioneer of modern ideas in the treatment of mental disease. Recognizing that psychiatry in this country will make little progress until voluntary clinics are established such as exist abroad, an endeavour has been made to advance by effecting a compromise between the real psychiatric clinic and the ordinary mental hospital. Situated three and a half miles from Cardiff, the hospital was opened in 1908 with immediate provision of 750 beds and administrative provision for 1,250. A chemical research laboratory has been organized, with a specialist staff; the original pathology laboratory has been greatly extended, and equipment for diagnosis and treatment such as is found in a modern general hospital has been installed. An out-patient department for the early psychoses and psychoneuroses, at the Royal Infirmary, has been conducted weekly for eight years from the Mental Hospital, and this is continued in the belief that the establishment of the necessary indoor clinic in psychiatry as part of, though not in contiguity with, the infirmary buildings is bound to be realized in time. The chemical research laboratory, started in 1910, was one of the earliest of the kind in a mental hospital in this country, and has published much valuable work. The successful effort to get Government recognition of research in mental hospitals by way of State aid owes much to the initiation of the Cardiff City Mental Hospital. A pioneer step as far as England and Wales is concerned—and probably the most drastic of the kind in this country as a whole—was the replacement of the system of male nursing by that of female nursing. With exception of three male wards the entire hospital is staffed by female nurses with, in some wards, a male for subordinate duties. The whole work of nursing is controlled by the matron, male supervising authority being abolished.

#### PRINCE OF WALES' HOSPITAL FOR LIMBLESS AND CRIPPLES.

This was opened in 1917, in the first place to deal with the limbless casualties of the war. It is now a general orthopaedic hospital supported by contributions, subscriptions, and endowment. It provides fifty beds and an out-patient department, and is very well equipped. Its work, which is ever extending, is thoroughly representative of modern orthopaedic surgery.

## UNION HOSPITAL.

The first hospital under the Poor Law in Cardiff was built in 1872. It has been enlarged repeatedly since, and now contains 300 beds for "acute sick"—not including the sick beds provided in the poor-house. It is being developed on modern lines, with a consultant staff. Many patients unable to enter the voluntary hospital on account of a large waiting list now seek admission here. Its work continues to expand so much that it has been decided to remove to a new building of 400 beds, with ample provision for expansion, about to be erected on a site on the confines of the city.

WELSH NATIONAL  
SCHOOL OF MEDICINE.

The School of Medicine was established in 1893 as part of the University College of South Wales and Monmouthshire, one of the constituent colleges of the University of Wales. It owed its inception largely to the advocacy of Dr. W. T. Edwards, President of the British Medical Association at the Cardiff Meeting in 1885, who took an active part in the early movement for higher education in the Principality. It was formally opened by Sir Richard Quain, the President of the General Medical Council. In addition to the early subjects of the medical curriculum it made provision for the teaching of anatomy, physiology, materia medica, and pharmacology, the clinical subjects of the fourth and fifth years being taken elsewhere. The School met with well-deserved success, and at the present time many of its students occupy distinguished positions on the staff of hospitals in London and elsewhere. Efforts were made from time to time to extend its scope, and in 1909 an increased grant from the Treasury led to a chair of pathology being founded. When the Haldane Royal Com-

mission on University Education in Wales was appointed it reviewed the whole position, and in its report in 1918 recommended that the School be completed, and that the departments of medicine and surgery be organized on the hospital unit system. The authorities of the Royal Infirmary having undertaken to make provision for those units within the hospital, the Treasury and other bodies agreed to furnish the necessary funds, and in 1921 the Welsh National School of Medicine, as it now became, was established with a full curriculum.

In the matter of buildings the School owes much to the munificence of Sir William James Thomas, Bt. His splendid gifts comprise the fine physiology block erected on the Newport Road, and the new building for the department of public health and school of preventive medicine completed a year ago—a group for which it would be difficult to find an equal in this country.

In 1924 the trustees of the Rockefeller Foundation made a grant of £14,000 to aid the medical unit. It covers the cost of a

laboratory in the Royal Infirmary for the department of medicine, the building of which was finished in 1927.

The controversy which has been waged between the University College and the University over the administration of the School since its completion has lately reached a settlement by way of compromise. It provides for the preliminary subjects remaining with the College, the clinical departments being made a separate school controlled by the University, and a special arrangement for anatomy and physiology. Whether such a solution is well adapted to deal with the growing complexity of medical education is a question upon which opinions may reasonably differ.

THE OLD "HAMADRYAD" HOSPITAL SHIP.

## THE SOUTH AFRICAN MEDICAL CONGRESS.

[FROM OUR CORRESPONDENT IN PRETORIA.]

The first Annual Scientific Meeting of the Medical Association of South Africa (B.M.A.) was held in Bloemfontein during the week commencing March 12th. This was the twenty-second South African Medical Congress, but the first since the profession in South Africa had been organized into a single united association affiliated with the British Medical Association. Owing to the central situation of Bloemfontein, the attendance of members was very good. This central situation in the Union makes it most convenient for congresses and conferences of all kinds. So often are these held in Bloemfontein that it has come to be known as the City of Conferences. It is the capital of a province the size of England, but with a population of only one million—200,000 Europeans and 800,000 natives. Bloemfontein was the capital of the old Free State Republic, and at the time of union of the provinces in 1910 the city, along with Capetown and Pretoria, made a bid for becoming the capital of the Union. Eventually the honours were divided; Capetown in the south, with its handsome houses of parliament, became the legislative capital, Pretoria in the north became the administrative capital, while Bloemfontein became the judicial capital.

The congress was officially opened by Mr. Justice Jacob de Villiers, judge of appeal in the Raadsaal. In an admirably framed address he gave first expression to a

feeling which pervaded all the proceedings: the duty of the profession to educate and guide the public so that a healthy nation might be produced.

*The Papers.*

That the profession is alive to this duty was demonstrated by the presidential address of Dr. C. Hugh Bidwell, who spoke on the subject of practical eugenics. In the previous congress at Pretoria Dr. Sanders, in the presidential address, had taken as his theme the text, "Every child has the right to be well born." Dr. Bidwell followed up this theme, and in an interesting and controversial paper showed how the general public could assist in this worthy object. In his opinion sterilization of feeble-minded and mentally deficient persons should be legalized as soon as public opinion could be educated up to it. Voluntary limitation of families he justified where there were recognized medical reasons, to secure adequate intervals between births, where paternal wages did not allow of further increase in the family, or where hereditary defects might possibly be transmitted. The State must decide that persons receiving public assistance should not have unlimited families. Should persons debarred by the State yet produce children they must be submitted to enforced segregation or sterilization.

Dr. E. G. Dru Drury opened the section of medicine and mental hygiene with a paper on the theory and practice of inhibition. This contained much valuable matter served up in an attractive and racy manner. Other useful

papers in this section were on repression, ankylostomiasis, hay fever, and action of extract of solanum pseudo-capsicum; but the outstanding contribution was a lecture on dental sepsis in its relation to general pathology by Sir Frank Colyer of the Royal Dental Hospital, London. His lecture, which was listened to with close attention, was illustrated by admirable lantern slides, the more remarkable in that many of them were from photographs taken years ago when x-ray photography was still in its infancy.

The opening paper in the surgical section was read by Professor Saint of Capetown University, on abdominal emergencies. This paper was of particular interest to the general practitioner in South Africa, on whom it is often incumbent to carry through an emergency abdominal case owing to the impossibility in many areas of obtaining assistance or transport. Fortunately difficult surgery is not usually involved, particularly if limited to life-saving measures. For an opening paper this was considerably shorter than the average, but it raised so many interesting points that a long and valuable discussion was evoked. Conditions in South Africa make it necessary for a large proportion of the profession to be able to do its own surgery. Interest in surgical matters is, therefore, always great, and shows itself in well-attended meetings and large numbers of papers on surgical matters at congresses. This was again the case at the present congress.

The public health section was opened with a paper which dealt with the medical practitioner's place in the local government and health administration of South Africa, read by Dr. Cluver. This continued the theme of Mr. Justice de Villiers. After a description of the organization of local government in South Africa some local problems were discussed, and some of the fields indicated in which the counsels of the profession were necessary for the successful development of the growing nation. There was considerable discussion on the various points raised in this paper. Dr. Brackenbury warned the members of the profession of the necessity for equipping themselves with preventive knowledge so as to be able to supply needed advice. Clinics and similar institutions for combating disease were growing up all round, and unless doctors co-operated with such bodies they were liable to be deprived of legitimate work. Other contributions in this section were a bio-sociological survey of the colour problem in South Africa by Dr. Hay Michel, who speaks with considerable authority on the subject; an instructive account and demonstration of the Schick and Dick tests and prophylactic inoculation against diphtheria and scarlet fever by Dr. Pratt Johnson; a paper on bacterial filtrates in the treatment of bacterial infections by Dr. G. Buchanan; and an address on bacteriophage in the prevention and treatment of experimental plague by Dr. J. H. Harvey Pirie.

Dr. Bruce-Bays opened the section of obstetrics and gynaecology with a paper entitled "The doctor, the midwife, and the patient," and Dr. F. B. Mudd the special subjects section with an account of anaesthesia in general and the general practitioner in particular.

#### *Distinguished Visitors.*

Only four visitors from outside South Africa attended congress. They were Dr. H. B. Brackenbury, Chairman of the Council of the British Medical Association; Sir Frank Colyer of the Royal Dental Hospital, London; Dr. H. B. Densham of Stockton-on-Tees; and Dr. C. D. Hatrick of New Barnet. These distinguished members of the parent Association were officially welcomed by Mr. Justice de Villiers when he opened the congress. At the same time he voiced the extreme regret and disappointment felt by all that the American colleagues who had contemplated attending this congress, under the auspices of the American College of Surgeons, had been unavoidably prevented from doing so. Very valuable services were rendered to the Association by Dr. Brackenbury, who came to attend the first annual general meeting of the Medical Association of South Africa as the official representative of the parent Association in Great Britain. His visit was made at considerable sacrifice to himself, and was very hurried. On the occasions when he addressed congress he spoke with the authority of useful experience, which is invaluable to an infant association such as the South African body. Sir

Frank Colyer's contribution to the medical section, which has already been referred to, was one of the outstanding features in congress, and is likely to influence profoundly the attitude of medical men in South Africa towards the matter of dental sepsis.

#### *Entertainments.*

The joint honorary secretaries of the local committee were three Bloemfontein ladies—Drs. Alico Cox, Marion Thomson, and Louisa Tomory. This probably accounted for the undoubted success of the social side of congress. Dancing was provided on three nights. After the presidential address on the first afternoon, Dr. and Mrs. Bidwell were at home in the Raadzaal grounds, and that night the mayoral reception was held in the town hall. On the Wednesday afternoon the Administrator's garden party was held in the Prince's Rose Garden—a garden which was laid down in 1925 to commemorate the visit of the Prince of Wales, and which has become one of the showplaces of Bloemfontein. On the remaining afternoons tennis, bowls, and other forms of amusement were provided at the Ramblers' Club. The entertainment was sufficiently varied to suit all tastes, and on the dance nights the few not so inclined played sedate bridge or attended theatrical performances.

#### *Trades Exhibition.*

The extensive exhibition of drugs and clinical appliances was housed in the Reitz Saal of the Grey University College. It was opened on the first morning by Dr. S. M. de Kock, vice-president of congress. All the well-known firms were represented. There were exhibits by Allen and Hainburys, Hind Brothers, Tacuber and Corssen, Potersen Ltd., H. K. Mulford, the Surgical Manufacturing Company of Johannesburg, Oppenheimer and Son, and Associated Proprietary Agencies.

## *Scotland.*

#### *Regius Professor of Physiology at Aberdeen.*

THE KING has appointed John James Rickard Macleod, D.Sc., LL.D., M.B., F.R.S., to be regius professor of physiology in the University of Aberdeen in place of Professor J. A. MacWilliam (resigned). Since 1918 Professor Macleod has held the chair of physiology in the Faculty of Medicine of the University of Toronto. After graduating in medicine at Aberdeen in 1898, he became demonstrator of physiology and lecturer in biochemistry at the London Hospital, and was Mackinnon Research Scholar of the Royal Society. From 1903 to 1918 he was professor of physiology in the Western Reserve University, Cleveland, Ohio. He was president of the American Physiological Society in 1922, and in the following year was elected F.R.S. and received jointly with Dr. F. G. Banting the Nobel Prize in medicine. In 1925 he was president of the Royal Canadian Institute, and he is an honorary Fellow or corresponding member of many medical and scientific bodies in Europe and America. He is the author of important works on physiology and biochemistry, more particularly in relation to carbohydrate metabolism and the introduction of insulin into therapeutics. The earliest accounts of the pioneer work on insulin by Macleod, Banting, and Best that appeared in this country were published in the *British Medical Journal* of July 22nd and September 9th, 1922; and on November 4th of the same year Professor Macleod contributed to our columns a general statement of the physiological and therapeutic effects of insulin. He will take up his new duties next autumn.

#### *Edinburgh Corporation and Venereal Disease.*

A public meeting was held in the Usher Hall, Edinburgh, on April 11th, under the auspices of the National Council of Women, in support of the Edinburgh Corporation's bill for compulsory powers in connexion with the treatment of venereal diseases. The Countess of Cassilis presided over a large attendance. Three of the members of Parliament for the city, Sir Patrick Ford, Sir Samuel Chapman, and Dr. Drummond Shiels, were present on the platform and spoke in support of the bill, while apologies for absence were intimated from Mr. William Graham, M.P., and Mr.

Jan MacIntyre, M.P., who expressed themselves as strongly in favour of the measure. Sir Patriek Ford commended the efforts which were being made in Edinburgh for the purpose of trying to stamp out the disastrous evils which might attend the diseases with which the bill proposed to deal. He said that he believed the modern medical view held that with proper repressive steps this disease could be almost stamped out in about ten years. He considered that the opponents of the bill were rash in doing anything to prevent a reasonable experiment being made in the carrying out of proper repressive measures. The matter had nothing whatever to do with party politics, as might be gathered from the fact that all shades of political opinion were represented among the Edinburgh members of Parliament, who were strong in support of the bill. He considered that there had been a great deal of hysterical talk and writing against this bill, but his personal opinion was that it did not go far enough, and that venereal disease should be made notifiable, just like diphtheria and other infectious diseases. The bill had been almost too much whittled down, he considered, on the ground that it was an infringement of the liberty of the subject; there should be no liberty to spread disease and disaster among one's fellow citizens. He said that the intimation of the Secretary of State for Scotland that the Government Whips would not be put on for the division on the bill in the House of Commons was a point gained, because the opinion of the House would now be free and untrammelled. Dr. Robert Forgan, executive medical officer for Lanarkshire, said that no one was going to suffer as the result of this bill if it became law, but everyone would benefit. The Edinburgh Branch of the British Medical Association had passed a resolution supporting the bill, and in the West of Scotland too there was a strong body of opinion in favour of compulsory treatment. He suggested that it would be greatly to the credit of Edinburgh if the city were the first in Scotland to take this important step forward. Dr. Laura Sandeman also spoke in favour of the bill. Dr. Drummond Shiels said that many people had been misled and prejudiced against the bill because the case had not been properly stated to them, but he believed that there had never been any forward step in medicine or public health without similar opposition. He was sure that the action of the Edinburgh Corporation would receive due recognition in future and more enlightened ages. The opponents of the bill talked about the liberty of the subject, but it was already part of the law of the land that there was no liberty of the subject to spread disease. Sir Samuel Chapman said that he wished to see the whole question thrashed out by an impartial committee of the House of Commons, and he would vote for the second reading of the bill because he believed this question should be thoroughly ventilated.

#### New Edinburgh Medical Appointment.

The Lord Provost's Committee of Edinburgh Town Council, at a meeting of the council held on April 5th, recommended that a new appointment of medical adviser to the corporation should be created to include the duties of casualty surgeon, medical referee, and medical officer for all departments of the corporation, with exception of the public health department; that the salary for the appointment be fixed at £500 per annum, and that Dr. Douglas Kerr be appointed to the office. An amendment was proposed to the effect that the recently appointed professor of forensic medicine in the University of Edinburgh should be elected to the office of casualty surgeon, and that Dr. Douglas Kerr should be retained as general medical adviser to the corporation to carry out the other duties. On a vote being taken, Dr. Douglas Kerr was appointed by the council to conduct all the duties of the post.

#### Hospital Co-operation in the West of Scotland.

A committee has been appointed for the western area of the Scottish Regional Committee of the British Hospitals Association to explore the needs of the area and consider the possibilities of co-operation. It is proposed to investigate not only the possibility of co-operation among the voluntary hospitals themselves, but also of co-operation

between the voluntary hospitals and the statutory authorities. In some of the municipal hospitals, it is stated, there are many empty beds, while the voluntary hospitals have long waiting lists. The appointment of the committee arises from a decision to institute an inquiry taken by the Regional Committee last October. At the meeting at which the committee was appointed it was stated that there are in the area 58 hospitals with 4,433 beds; of this total 16 hospitals in Glasgow have 2,547 beds, the remainder being spread over the ten counties which make up the rest of the area.

## Ireland.

#### The Late Dr. H. L. McKisack.

THE obituary notice of Dr. Henry Lawrence McKisack, consulting physician to the Royal Victoria Hospital, Belfast, which appeared in the *British Medical Journal* of April 7th, mentioned that he served as president of the Ulster Branch of the British Medical Association in 1914-15; this, however, was by no means the only office held by him in the Association. Dr. McKisack was a member of the North of Ireland Branch Council in 1896, in 1899, and again in 1902, and was for a year vice-president of the Branch. In 1903 he was elected to the Ulster Branch Council, and was re-elected in 1908, after serving for a year as Chairman of the Belfast Division. When the British Medical Association held its Annual Meeting at Belfast in 1909 he acted as local honorary general secretary, and in the following year he held office as vice-president of the Section of Medicine. He was a member of the Central Council of the Association in 1908-09, and in the latter year was elected to the Irish Committee.

#### Proposed Memorial.

Steps have been taken by an influential group of colleagues in Belfast to establish a permanent memorial to Dr. McKisack, who was not only a wise physician, but was beloved by all who knew him. A circular letter has accordingly been issued in order that his many friends, both lay and medical, may be given an opportunity to associate themselves with the project. It is suggested that subscriptions should be limited to a maximum of two guineas, that the subscribers should at a later date decide what form the memorial should take, and that it should be associated with the Royal Victoria Hospital, Belfast, to which he rendered such long and useful service. Subscriptions may be sent to Mr. Edwin D. Hill (Head Office, Northern Bank, Belfast) or Mr. Stanley Ferguson (Head Office, Ulster Bank, Belfast), who are acting as honorary treasurers, or to any of the signatories to the appeal: Dr. William Calwell, Dr. C. K. Darnell, Professor Andrew Fullerton, Dr. James Graham, Sir Thomas Houston, Professor R. J. Johnstone, Mr. T. S. Kirk, Professor J. A. Lindsay, Professor J. E. MacIlwaine, Dr. Robert Marshall, Dr. J. C. Rankin, Dr. Robert Reid, Professor W. W. D. Thomson, and Mr. Malcolm Brice Smith.

#### Irish Free State Medical Register.
